ABSTRACT

5 The goal of this study is to challenge a large eddy simulation model with a range of observations
6 from a modern field campaign and to develop case studies useful to other modelers. The 2015
7 Cloud System Evolution in the Trades (CSET) field campaign provided a wealth of *in situ* and
8 remote sensing observations of subtropical cloud transitions in the summertime Northeast Pacific.
9 Two Lagrangian case studies based on these observations are used to validate the thermodynamic,
10 radiative and microphysical properties of large eddy simulations (LES) of the stratocumulus to
11 cumulus transition. The two cases contrast a relatively fast cloud transition in a clean, initially
12 well-mixed boundary layer vs. a slower transition in an initially decoupled boundary layer with
13 higher aerosol concentrations and stronger mean subsidence. For each case, simulations of two
14 neighboring trajectories sample mesoscale variability and the coherence of the transition in adjacent
15 air masses. In both cases, LES broadly reproduce satellite and aircraft observations of the transition.
16 Simulations of the first case match observations more closely than for the second case, where
17 simulations underestimate cloud cover early in the simulations and overestimate cloud top height
18 later. For the first case, simulated cloud fraction and liquid water path increase if a larger cloud
19 droplet number concentration is prescribed. In the second case, precipitation onset and inversion
20 cloud breakup occurs earlier when the LES domain is chosen large enough to support strong
21 mesoscale organization.

22 **Significance Statement**

23 Low-lying clouds over the ocean are difficult to represent in global climate models and contribute
24 to uncertainty in climate predictions. To improve understanding and simulation of these clouds,
25 an intensive airborne measurement campaign in 2015 over the Northeast Pacific Ocean sampled
26 these clouds and the surrounding air mass as the trade winds carried them towards Hawaii. In
27 this paper, we simulate two contrasting case studies from this campaign with a high-resolution
28 model that captures cloud-scale motions and processes. The observations test the model's fidelity
29 in representing the transition from widespread to broken cloud cover, while the model suggests
30 that this transition is accelerated by weather conditions promoting unusually weak subsidence and
31 by the onset of drizzle.

32 **1. Introduction**

33 Stratocumulus clouds cover broad swaths of the oceans and play a significant role in causing
34 spread in global climate model predictions due to uncertainties in representing their cloud feedbacks
35 and aerosol-cloud interactions (Boucher et al. 2013; Wood 2012). Over the eastern subtropical
36 oceans, stratocumulus form in cool and moist air masses capped by warm, dry air subsiding in the
37 descending branch of the Hadley circulation. Trade winds carry these air masses westward and
38 towards the equator over progressively warmer sea surface temperatures (SST), leading to the deep-
39 ening and decoupling of the marine boundary layer (MBL) and the breakup of the stratocumulus
40 cloud layer into patches of shallow cumuli (e.g., Bretherton and Wyant 1997).

41 These cloud transitions have been long studied through field campaigns (e.g., Albrecht et al.
42 1995), remote sensing observations (Pincus et al. 1997; Sandu et al. 2010; Eastman and Wood
43 2016) and simulations (Krueger et al. 1995; Wyant et al. 1997; Sandu and Stevens 2011; Van der
44 Dussen et al. 2013; De Roode et al. 2016; Neggers et al. 2017) in an effort to identify key controls,

45 such as inversion stability (Klein and Hartmann 1993; Sandu and Stevens 2011), increasing latent
46 heat fluxes over warmer SSTs (Bretherton and Wyant 1997), subsidence (Van der Dussen et al.
47 2016), free tropospheric humidity (Klein et al. 1995; Sandu and Stevens 2011; Eastman and Wood
48 2018) and aerosol and its feedback with precipitation (Sandu and Stevens 2011; Eastman and Wood
49 2016; Yamaguchi et al. 2017).

50 While many simulation studies are based on idealized or composite scenarios with gradual
51 changes in SST and steady large-scale forcings, a case study based on the ASTEX field campaign
52 (Bretherton and Pincus 1995; Bretherton et al. 1999; Van der Dussen et al. 2013) provided an
53 example of a particular strongly-forced transition. McGibbon and Bretherton (2017) also simu-
54 lated well-observed cloud transitions from the MAGIC campaign in the northeast Pacific along
55 trajectories that followed the path of a well-instrumented container ship. Following in the mold
56 of those studies, this paper focuses on the simulation of two transition cases well-observed using
57 modern airborne in situ and remote sensing instrumentation during the Cloud System Evolution
58 in the Trades (CSET) field campaign. The goal of this study is to challenge an LES with a range
59 of observations from a modern field campaign. By evaluating the simulations against a range of
60 observations, including in situ measurements, aircraft-borne radar and lidar and satellite-based
61 remote sensing, the model cannot be tuned to match a particular observation. In addition to the
62 initial exploration of these cases in the present paper, we hope that these Lagrangian case studies
63 will be used by other researchers to illuminate the processes that control real cloudiness transitions.

64 The CSET field campaign (Albrecht et al. 2019) took place over the Northeast Pacific Ocean
65 in July and August 2015. The cloudy marine boundary layer was sampled close to the California
66 coast by the NCAR Gulfstream V (GV) aircraft on westward flights from Sacramento, California
67 to Kona, Hawaii. The GV performed repeated sampling patterns, called modules, that characterize
68 the boundary layer, cloud and precipitation along with the lower free troposphere. Each module

69 included a downward flight leg from the free troposphere into the subcloud layer, followed by level
70 legs in the subcloud and cloud layer and repeated upward and downward legs across the inversion.
71 (See figure 4 of Albrecht et al. (2019) for an example.) Using HYSPLIT trajectories (Stein et al.
72 2015) based on the Global Forecast System and Global Data Assimilation System analysis from
73 the National Centers for Environmental Prediction, the eastward return flight two days later was
74 planned so that the same boundary layer air masses would be sampled again by the GV. In addition
75 to in situ cloud, aerosol and meteorological probes, the GV also carried a High Spectral Resolution
76 Lidar and the W-band HIAPER Cloud Radar (HCR) that provided remote observations of cloud,
77 aerosol and precipitation. Satellite observations and reanalysis complement observations from the
78 GV and provide both broader context for cloud changes and continual coverage between the times
79 when an air mass is sampled by a research flight. Bretherton et al. (2019) describe the northeast–
80 southwest progression of the transition in a composite of data from the various research flights,
81 finding that cloud cover is related to inversion strength in a manner consistent with climatology.
82 They also find no clear correlation between cloud cover and cloud droplet number concentration
83 across observations during CSET, after accounting for the effect of estimated inversion strength
84 (EIS, Wood and Bretherton 2006) on cloud fraction.

85 Complementing this view of the average progression of the transition, Mohrmann et al. (2019)
86 studied the Lagrangian evolution of individual air masses that were observed by a full module by
87 the GV during both the westward research flight and the return flight two days later. Below-cloud
88 observations of chemical tracers showed strong coherence between the air masses, suggesting that
89 the trajectories were Lagrangian. Eighteen Lagrangian case studies were compiled from CSET.
90 Many of these case studies included multiple trajectories that sample some of the diversity in the
91 forcing and timing of the transition within each air mass, as documented in Mohrmann et al. (2019).
92 In this paper, the transition is defined to be complete when the cloud fraction falls below 50% and

93 remains below 50% for the following 24 hours. However, as our interest here is in the simulation of
94 cloud evolution during the transition, we will not emphasize the completion time of the transition
95 in this work.

96 From this collection, we select two cases with contrasts in aerosols, decoupling and the pace of
97 the transition for simulation. The first case, L06, encompasses research flights RF06 and RF07 on
98 July 17 and 19, 2015, respectively, and occurs in a clean MBL ($N_d \sim 40 \text{ cm}^{-3}$) where large-scale
99 forcings promote rapid boundary layer deepening. Toward the end of this case, RF07 sampled
100 ultra-clean layers with total aerosol (interstitial aerosol plus cloud droplet) concentrations less than
101 10 cm^{-3} (Wood et al. 2018). The second case study, L10, spans RF10 and RF11 on July 27 and 29
102 and includes a deeper, more decoupled initial boundary layer with higher aerosol concentrations
103 ($N_d \sim 200 \text{ cm}^{-3}$) that experiences slower MBL deepening and a delayed cloud transition when
104 compared to the first case study. These flights were also a focus of study in Albrecht et al. (2019)
105 and Sarkar et al. (2020).

106 Aerosols affect the transition through precipitation formation, which itself impacts latent heating,
107 decoupling, entrainment and the delivery of moisture to the inversion layer by cumulus updrafts
108 (e.g., Albrecht 1993; Stevens et al. 1998; Yamaguchi et al. 2017). The removal of aerosols
109 by collision and coalescence during precipitation formation was also found by Yamaguchi et al.
110 (2017) to encourage further precipitation downstream and the breakup of inversion cloud in idealized
111 simulations of the transition that included a prognostic treatment of aerosol. Such processes were
112 also likely at work during CSET in the formation of ultra-clean layers (Wood et al. 2018). Clearly,
113 it is desirable to simulate these transitions using a model that predicts aerosol concentrations and
114 includes collision-coalescence effects on aerosol. However, the CSET field experiment was not
115 designed to fully constrain the initial and boundary conditions required for a simulation of these
116 Lagrangian case studies with prognostic aerosols. The aerosol environment during CSET was

117 highly variable (Bretherton et al. 2019, Fig. 12) and is poorly constrained except at the time of
118 the two research flights. Those flights also included limited sampling of the free troposphere. As
119 a result, in these first simulations of L06 and L10, we choose to prescribe cloud droplet number
120 concentrations based on observations during the research flights.

121 This paper describes simulations of these two cases and makes detailed comparisons against
122 the wealth of observations from CSET. The observations and modeling approach are described in
123 section 2. The results from the two case studies are described in sections 3 and 4. In section 5,
124 simulations that combine conditions from the two cases are used to explore their impact on the
125 transition. Conclusions are presented in section 6.

126 **2. Methods and Data**

127 *a. Observations and Reanalysis*

128 To facilitate the simulation of the Lagrangian case studies from CSET, Mohrmann et al. (2019)
129 compiled observations and reanalysis along each trajectory associated with a case study.¹ Satellite
130 retrievals provided radiative fluxes from the Geostationary Operational Environmental Satellite-15
131 (GOES-15, hereafter GOES) and Clouds and the Earth's Radiant Energy System (CERES, Doelling
132 et al. 2016), liquid water path from the Special Sensor Microwave Imager (SSM/I, Wentz et al. 2012)
133 and cloud properties from GOES (Minnis et al. 2008), while the ERA5 reanalysis (Hersbach et al.
134 2020) provided information about meteorological profiles (including ozone), large-scale vertical
135 motion, and large-scale horizontal advective tendencies, which were computed relative to the

¹Several trajectories were initialized along each westward research flight, numbered consecutively from west to east. Subsets of these trajectories were assembled into Lagrangian case studies if they were sampled by the same modules during the westward and eastward research flights (Mohrmann et al. 2019, sec. 2.a.2). For example, Lagrangian case study L10 includes trajectories 5.5 and 6.0, with trajectory 5.5 (abbreviated L10 Tr5.5) lying to the southwest of trajectory 6.0 during the passage of RF10. Further details are available at <http://catalog.eol.ucar.edu/cset/tools/missions> under "Airmass Trajectory Analysis".

136 motion of the trajectory. Both reanalysis and satellite data were averaged over a $2 \times 2^\circ$ box centered
137 on the trajectory. When GOES data is compared with simulations, uncertainty is estimated by
138 the range of averages in $2 \times 2^\circ$ boxes centered on and to the northeast, northwest, southwest and
139 southeast of the trajectory. The uncertainty of SSMI and CERES depicts two standard errors of
140 the mean.

141 The intersections of the GV aircraft flight path with the trajectories provide a brief but com-
142 prehensive view of the state of the atmosphere and boundary layer at the sampling time. In situ
143 measurements from the GV provide information about meteorology, aerosol and cloud properties,
144 while the GV's radar and lidar observe the cloud and precipitation structure. In situ measurements
145 from the GV are presented as a single sounding from the downward flight leg at the start of a
146 sampling module (e.g., Albrecht et al. 2019), with an estimate of mesoscale variability based on all
147 observations within 2.5° of the downward flight leg. This region is larger than the $2 \times 2^\circ$ box over
148 which the forcings and GOES observations are averaged but is a better choice given the limited
149 sampling of the GV along a linear path. Vertical wind variance is computed based on 20-second
150 windows around the measurement time and is inflated to account for scales beyond the 20-second
151 window following Atlas et al. (2020, eqn. 1-2).

152 Radar and lidar observations (Schwartz et al. 2019) from the GV aircraft provide profiles of
153 hydrometeor fraction, precipitation fraction (defined as $Z > -10$ dBZ, i.e., including drizzle) and
154 conditional averages of radar reflectivity where precipitation is present. In this paper, a newly
155 calibrated dataset (V. Ghate, personal communication) is used, which is based on Ghate and
156 Schwartz (2020). The radar and lidar on board the GV switched from downward- to upward-
157 pointing during the flight depending on the GV's altitude, and, at each height, data is averaged over
158 times when that height is in the radar or lidar's field of view and beyond the dead zone close to the
159 plane (Ghate et al. 2016). As with the in situ measurements, each average is based on locations

160 along the GV flight path within 2.5° of the downward flight leg, with uncertainty estimated using
161 the standard error of that average.

162 When comparing our simulation results to these observations, we will declare agreement of
163 the simulations with observations when the simulated results lie within the band of uncertainty
164 around the observed quantity. As these uncertainty estimates mainly represent sampling or spatial
165 uncertainty and neglect other uncertainties in the observations and in the model forcings, they
166 probably underestimate the overall uncertainty.

167 *b. Simulation Design*

168 Along the Lagrangian trajectories, the air masses are forced by the evolving sea surface tempera-
169 ture (SST) as well as large-scale subsidence, horizontal advection and pressure gradients extracted
170 from ERA5 along HYSPLIT trajectories (Mohrmann et al. 2019). Figure 1 shows salient features
171 of these forcings.

172 While the trajectory is based on winds at a constant height of 500 m and is designed to roughly
173 follow the boundary layer air mass, vertical wind shear will lead to non-zero horizontal advective
174 tendencies at other levels. As seen in Figure 1c-d, the time-averaged horizontal advective tendencies
175 between each pair of research flights are indeed close to zero in the lowest kilometer, but non-zero
176 tendencies are present in deeper boundary layers and in the free troposphere. The large-scale
177 forcings include back trajectories to 00Z on the day of the westward flight leg (about 16 hours in
178 advance of the flight) and forward trajectories that end approximately one day after the air mass is
179 re-sampled by the eastward flight. As a result, the simulations last roughly 3.75 days. In each case
180 considered in this paper, they include large changes in MBL depth and cloud cover.

181 The early part of each simulation is designed to produce a turbulent cloudy boundary layer
182 whose mean profiles reproduce in situ observations at the time when the westward research flight

183 intersects the trajectory. This also allows for some development of mesoscale variability before that
184 time. Reference profiles for the time of the first research flight are based on in situ observations.
185 For liquid-water temperature, they are based on in situ observations during the downward flight
186 leg at low levels and ERA5 aloft, blended in a layer above the inversion². The simulations are
187 intended to represent average conditions within a region around the Lagrangian trajectory. As the
188 downward flight leg moisture soundings were not always representative of the conditions in the
189 broader area around the soundings, the total water profile is derived from the observed relationship
190 between total water and liquid-water potential temperature in GV observations across a broad
191 region within 2.5 degrees of the downward flight leg. Using the resulting relationship $q_t = q_t(\theta_l)$,
192 the reference total water profile is computed as $q_t(z) = q_t(\theta_l(z))$, where $\theta_l(z)$ is the reference θ_l
193 profile. This also defined a reference relative humidity profile. Before the time of the first research
194 flight, the reference temperature profile within the boundary layer is reduced in lockstep with the
195 change in SST along the Lagrangian trajectory, and the reference humidity is changed to preserve
196 the reference relative humidity profile in the boundary layer.

197 Before the time of the first flight, the domain-mean liquid-water temperature and total water
198 profiles are nudged to these reference profiles that evolve with SST as described above. The
199 nudging timescale is three hours within the boundary layer and ten minutes above the boundary
200 layer. As the uncertainty of observations is largest around the inversion, no nudging is applied
201 within 50 m of the inversion. However, the large-scale vertical velocity is also modified using a
202 weak temperature gradient approach (Blossey et al. 2009) during this period to keep the simulated
203 inversion close to its observed altitude. This nudging and weak temperature gradient method
204 gradually switch off over a ninety minute period before the westward research flight.

²In this paper, the inversion is defined as the height where the function $f(z) = \langle d\bar{\theta}_l/dz \rangle \langle d\overline{RH}/dz \rangle$ is minimized. Here, RH is relative humidity, and the overbar denotes a horizontal average.

205 The winds are initialized from the ERA5 winds and are forced by geostrophic winds derived
206 from ERA5 geopotential gradients. In addition, the horizontally-averaged wind profile is nudged
207 to ERA5 on a slow, 12 hour timescale at all heights. This nudging minimizes inertial oscillations
208 in the wind field arising from mismatches between the initial state or differences in the momentum
209 fluxes in ERA5 and the simulations here. The GV-observed winds are not used in the model
210 because they may not be consistent with the geostrophic winds derived from ERA5 and might
211 excite inertial oscillations.

212 After the time of the first flight, the temperature and moisture profiles are nudged towards those
213 of ERA5 starting 500 m above the inversion. Except for the weak nudging of the domain-mean
214 winds, the marine boundary layer and the inversion layer are allowed to evolve without nudging
215 following the time of the first research flight. This approach tests the ability of an LES model to
216 follow the evolution of the air mass along the Lagrangian trajectory as observed by GOES and to
217 match the in situ and remote sensing observations made during the second, eastward research flight
218 as discussed in Sections 3 and 4.

219 *c. Modeling Framework*

220 Large eddy simulations are performed with the System for Atmospheric Modeling (SAM)
221 (Khairoutdinov and Randall 2003), version 6.10.9. SAM employs the anelastic approximation
222 and periodic boundary conditions in the horizontal directions. The model’s conserved thermody-
223 namic variable is liquid-water static energy, $s_l = C_p T + g z - L_v q_{liq}$, where T is temperature, c_p the
224 specific heat of dry air at constant pressure, g gravity, z altitude, L_v the latent heat of vaporization,
225 and q_{liq} the mass mixing ratio of liquid condensate (e.g., cloud liquid plus rain). Using the Mor-
226 rison microphysics (Morrison et al. 2005) with only liquid-phase processes enabled, the advected
227 microphysical quantities are the mass mixing ratios of total water (vapor plus cloud liquid) and rain,

228 along with the number mixing ratio of rain. Cloud droplet number concentration is specified as dis-
229 cussed in the next subsection. Radiative fluxes and heating are computed with the Rapid Radiative
230 Transfer Model for GCM Applications (RRTMG) (Mlawer et al. 1997). Cloud optical properties
231 are computed by the parameterizations of CESM (Neale et al. 2010, Sec. 4.9.3) using information
232 about the cloud droplet size distribution from the Morrison microphysics. An ISCCP simulator
233 (Klein and Jakob 1999) has been implemented that uses model outputs to predict satellite-inferred
234 cloud fraction, which will be compared to GOES observations along the Lagrangian trajectory. A
235 cloud radar simulator, QUICKBEAM (Haynes et al. 2007), estimates the 94 GHz radar reflectivity
236 associated with the modeled cloud and precipitation fields for comparison with the GV HCR.

237 The configuration of simulations in this paper are described in Table 1, including the times of
238 the simulation start and passage of the research flights as well as specifications of domain size,
239 horizontal grid spacing, cloud droplet number concentration, which are discussed more fully below.
240 Domain sizes in the horizontal range from 9.6 to 86.4 km square with horizontal grid spacings of
241 100 m and 200 m in the smallest and largest domain, respectively. An intermediate domain size,
242 28.8 km square, is simulated with both horizontal resolutions to explore the effect of horizontal
243 grid spacing in isolation. The vertical grid uses 432 levels with grid spacing of 10 m from 950 m
244 to 3800 m, which covers the range of inversion heights in the simulations. The model top is at
245 6 km, and a damping region is applied in the top 30% of domain to prevent the reflection of gravity
246 waves. Since the model domain ends in the middle troposphere, computations of radiative fluxes
247 and heating include upper air soundings of temperature, moisture and ozone from ERA5 above the
248 model soundings.

249 *d. Specification of Cloud Droplet Number Concentration*

250 Droplet concentrations N_d were reported for flights at the beginning and end of the two case
251 studies by Mohrmann et al. (2019). However, N_d was spatially variable, so we use a more elaborate
252 approach to estimate the N_d along the trajectories that is specified in the LES.

253 Our approach is based on in situ observations of accumulation mode aerosol number concen-
254 tration N_a and cloud droplet number concentrations N_d . We first consider case L06. Figure 2a
255 shows N_a , estimated as the particle number concentration outside of clouds in the 100-1000 micron
256 diameter range detected by the GV UHSAS instrument and N_d from the GV Cloud Droplet Probe
257 (CDP), near where the westward research flight RF06 crossed Trajectory 2.3. Within the MBL
258 (below 1 km), N_a and N_d both scatter around 40 cm^{-3} . The return flight, RF07, found even cleaner
259 conditions two days later (Figure 2b), with N_a and N_d near 10 cm^{-3} within the cloud layer, despite
260 higher aerosol concentrations $N_a > 100 \text{ cm}^{-3}$ above the trade inversion. Wood et al. (2018) noted
261 numerous ultra-clean layers (N_a or $N_d < 10 \text{ cm}^{-3}$) during RF07.

262 For comparison, Figure 2c show GOES retrievals (daytime only) of the median value of N_d
263 along the trajectory. Like the in-situ observations, the GOES N_d decreases in time. However, the
264 GOES retrievals are smaller than the in situ observations during the westward flight RF06, likely
265 due to biases associated with cloud inhomogeneities over the ~ 9 km pixel size for this product.
266 This tendency for GOES to underestimate N_d was found by Bretherton et al. (2019) to hold across
267 many of the CSET flights, with a stronger bias in more broken cloud regions closer to Hawaii.
268 (See Figure 14 in Bretherton et al. (2019) and the accompanying discussion.) Thus we do not use
269 GOES-retrieved N_d as the primary information to specify LES N_d along a trajectory, and we accept
270 that N_d concentrations are somewhat uncertain between the two flights.

271 Figure 2c also shows the prescription of N_d for the different simulations of L06 Tr2.3, which is
272 summarized in Table 1. Two simulations, the reference simulation Lx29 and the smaller-domain
273 Lx10, use a time-varying N_d that approximates our best estimate of the evolution in N_d from RF06
274 to RF07. Lacking any comparable in situ measurements before, after or between the two research
275 flights, we choose a parsimonious prescription for the time evolution of N_d : constant values of 40
276 cm^{-3} before RF06 and 10 cm^{-3} after RF07, with linear variation in time between the two flights.
277 Simulations with prognostic aerosols (Yamaguchi et al. 2017) suggest that collision-coalescence
278 scavenging of aerosol can lead to more abrupt changes in N_d , but the lack of information about
279 precipitation formation between the research flights argues for a simpler approach, such as the one
280 adopted here. Three other simulations, Nd10, Nd20 and Nd40, have constant values of N_d in time
281 and are used to explore the sensitivity of cloud, precipitation and MBL structure to N_d in case L06.

282 During the first, westward research flight RF10 of Lagrangian case study L10, higher MBL
283 aerosol concentrations are observed near trajectory Tr6.0 with smaller aerosol concentrations aloft
284 (Fig. 2d), so that the aerosol gradient across the inversion is reversed from that seen during RF07
285 (Fig. 2b). There is a large scatter in N_d in RF10, but we choose $N_d = 200 \text{ cm}^{-3}$ as the specified N_d
286 at this time. At the time of the return flight RF11 (Fig. 2e), aerosol concentrations in the MBL have
287 a strong vertical gradient. While the mean value in the larger mesoscale region (blue circles in
288 Fig. 2e) range from $\sim 200 \text{ cm}^{-3}$ at low levels to 100 cm^{-3} in the layer with cloud, concentrations as
289 small as 20 cm^{-3} are observed in the cloud layer during the downward flight leg (blue dots). There
290 is also a vertical gradient in cloud droplet number concentration. An intermediate value of $N_d =$
291 50 cm^{-3} is chosen as the specified N_d for the simulations at the time of RF11. As in L06, the cloud
292 droplet number concentration in L10 is assumed to evolve linearly in time between the RF10 and
293 RF11 sampling, with constant values before RF10 and after RF11 (Fig. 2f). As for RF06 above,
294 GOES retrievals of N_d tend to underestimate in situ observations during both RF10 and RF11.

3. Case L06 (RF06/RF07) results

Along the two neighboring trajectories, Tr2.3 and Tr3.0, that are part of Lagrangian case L06, the large-scale vertical velocity from ERA5 indicates mean ascent at low levels during the interval between RF06 and RF07 (Fig. 1b). This allows substantial deepening of the marine boundary layer. Consistent with this weak large-scale convergence, the two trajectories (shown in Fig. 3a) remain roughly equidistant (do not horizontally diverge) throughout the case study. While GOES indicates nearly full cloud cover at the time of RF06 near the two trajectories, there is broken cloud nearby (Fig. 3b). One day later, inversion cloud has broken up in a region of several hundred kilometers around the two trajectories (Fig. 3c). At the time of RF07 and a day later, shallow cumulus convection dominates the cloud cover (Fig. 3d-e).

As described above in Section 2b, the simulations of L06 begin with period of strong nudging and adaptive large-scale vertical motion that is designed to drive the domain-mean soundings of temperature and moisture towards those observed during RF06, while also allowing turbulence, convection and mesoscale circulations within the boundary layer to develop. Following the passage of RF06, the Lagrangian evolution of the boundary layer is influenced mainly by the sea surface temperature and large-scale forcings from ERA5 (Fig. 1a and 4a-f, respectively). Because these Lagrangian trajectories were computed from wind velocities in the boundary layer, the large-scale horizontal advection of temperature and moisture (Fig. 4c-f) is weak at low levels, but — due to wind shear — it does impact the free troposphere and the layer near the ERA5 inversion. Transient variations in the large-scale forcings are most visible in the large-scale vertical velocity w_{LS} , with frequent changes in the sign of w_{LS} during the three days following RF06 (Fig. 4a-b). The simulated inversion height tracks that of ERA5 in these cases, so that the large-scale horizontal advection will be similar in the boundary-layer-integrated energy and moisture budgets in ERA5 and the

318 simulations here. The forcings and ERA5 relative humidity (Fig. 4g-h) display modest differences
319 between the trajectories. For example, below-inversion air is more humid in Tr3.0 than Tr2.3
320 for the day following RF06. The simulated time-height profiles of cloud fraction (Fig. 4i-j) echo
321 the differences in relative humidity between the two trajectories, as the near-inversion cloud lasts
322 longer in Tr3.0 than Tr2.3 and persists through the day of 18 July before breaking up the following
323 night.

324 The air masses along these two trajectories are forced by warming SSTs and mean ascent at low
325 levels, and they experience a strong decrease in cloud cover between the two research flights. To
326 better understand these cases, the evolution of a single reference simulation, Lx29 along L06 Tr2.3
327 (Fig. 4i), is first described in detail. Then, the sensitivity of the simulated meteorology, cloud
328 and precipitation to domain size, prescribed cloud droplet number concentration and choice of
329 trajectory (i.e., Tr2.3 vs. Tr3.0) are explored.

330 *a. Reference L06 Simulation: Lx29*

331 In Figure 5a-c, profiles of potential temperature, water vapor mass mixing ratio and relative
332 humidity at the time when RF06 intersected Tr2.3 are compared against in situ observations and
333 ERA5 reanalysis. As the simulation is strongly nudged towards the sounding before this time, the
334 potential temperature profile (Fig. 5a) reproduces the in situ profile well, though the inversion layer
335 is slightly thicker in the observations. There is little mesoscale variability of potential temperature
336 within the boundary layer but a regional spread in inversion height. ERA5 reproduces the observed
337 temperature profile well. The moisture profile (Fig. 5b) — which is nudged to the mesoscale mean
338 conditions before RF06 — is moister than the downward leg and on the upper edge of the regional
339 distribution of q_v . In the lowest few hundred meters, the modeled q_v is closest to ERA5, which
340 may result from the wind forcing and SSTs being derived from that reanalysis. Simulation Lx29 is

341 more decoupled than ERA5 and the downward flight leg. Above the inversion, the downward flight
342 leg is moister than ERA5 and the mesoscale mean. Weaker-than observed meridional winds within
343 the MBL in Lx29 (Fig. S1b) lead to low surface wind speeds and a low bias in latent heat fluxes
344 relative to ERA5 (Fig. S2b) around the time of RF06. The vertical velocity variance (Fig. S1c) is
345 stronger than observed near the LCL but lies within the observed range elsewhere in the MBL.

346 In Figure 5d-f, simulated radar reflectivities are used to compare the simulated and observed
347 hydrometeor and rain fractions and the conditionally-averaged reflectivity of rain (using a -10 dBZ
348 threshold for rain). To improve sampling, the radar and lidar data are sampled across the larger
349 mesoscale region with 2.5° of the downward flight leg. Thus, as with the mesoscale in situ data, they
350 sample a representative range of inversion heights. The simulated hydrometeor fraction (Fig. 5d)
351 agrees well with the observations, though the hydrometeor fraction exceeds the observations below
352 500 m altitude. The rain fraction, which also includes drizzle, is biased high at low levels but closer
353 to the observations within the cloud layer. The intensity of drizzle/rain (Fig. 5f) is well-represented
354 in Lx29. Note that the radar switched from upward- to downward-pointing mode as the aircraft
355 changed altitude within and above the MBL, so the observational sampling is nonuniform in the
356 vertical and can lead to discontinuities, such as that seen at ~ 400 m altitude in Figure 5f.

357 In Figure 6a-e, simulated cloud properties and radiative fluxes are compared with GOES re-
358 trievals. The simulated cloud fraction (Fig. 6a) matches the trend in GOES cloud fraction in
359 general, though Lx29 underpredicts GOES at the time of RF06 and again during the night before
360 RF07. Median cloud top height and top-of-atmosphere (TOA) albedo in Lx29 also reproduce those
361 retrieved from GOES and TOA albedo retrievals from CERES (Fig. 6b-c). GOES and CERES
362 retrievals of outgoing longwave radiation (OLR) agree with Lx29 during the second half of the
363 simulation, but the two OLR retrievals disagree themselves for about a day following RF06, with
364 Lx29 lying in between (Fig. 6d). The disagreement in OLR between GOES and CERES is likely

365 related to the differing retrieval algorithms and the inclusion of polar-orbiting satellite data in the
366 CERES retrievals (Minnis et al. 2008; Doelling et al. 2016). The GOES- and SSMI-retrieved liquid
367 water path (LWP, Fig. 6e) is larger than simulated by Lx29 through much of the case study, but
368 SSMI retrievals and Lx29 agree at some times, in particular during RF06 and the last 12 hours of
369 the simulation. Lastly, Figure 6f shows the accumulated surface precipitation in the model simula-
370 tions. In Lx29, surface precipitation begins during the night after RF06 and continues through the
371 simulation, with a prominent diurnal cycle during the last two days that is matched by overnight
372 increases in entrainment (Fig. S2c).

373 The modeled profiles of θ , q_v and relative humidity simulated by Lx29 during RF07 also agree
374 well with those measured by the GV (Fig. 7a-c). The inversion is slightly (~ 50 m) shallower and the
375 cloud layer slightly colder than observed, with the modeled humidity inversion lying on the bottom
376 edge of observed mesoscale variability of inversion height (~ 2250 – 2550 m) and the downward
377 GV leg (brown dots) on the top edge (Fig. 7b). While ERA5 accurately represents the observed
378 inversion height, the cloud layer in ERA5 is drier than observed. In simulation Lx29, the cloud
379 layer has a dry bias in q_v . As the relative humidity is well predicted, we attribute the q_v bias to
380 a bias in θ . As during RF06, the meridional wind is weaker than observed at the time of RF07
381 (Fig. S3). At both times, the modeled winds lay closer to the geostrophic than observed winds.

382 The lidar and radar retrievals of cloud and precipitation properties are a challenging comparison
383 for the LES, requiring fidelity in simulating both cloud structure and cloud microphysics. While
384 the simulated hydrometeor and drizzle/rain fraction slightly underpredict the retrieved values in
385 the upper part of the cloud layer (above ~ 1300 m), both fractions are overpredicted at lower levels
386 (Fig. 7d-e). Conversely, the intensity of precipitation (Fig. 7f) agrees well with observations at
387 low levels and is over-predicted at upper levels. Some of these errors in the vertical structure of

388 cloud and precipitation may be associated with the use of a single prescribed value of N_d , as in situ
389 observations (Fig. 2b) display a significant vertical gradient of N_d and N_a within the MBL.

390 The simulated spatial structure of cloud and precipitation in Lx29 is shown in Figure 8, with
391 roughly daily 2D snapshots of liquid water path and 3D visualizations of clouds and precipitation
392 through the simulation. At the time of RF06 (Fig. 8a-b), the cloud field has already developed
393 organization during the spin-up phase of the simulations with multiple cells of drizzling stra-
394 tocumulus, and cold pools are visible in the density temperature anomaly field T'_ρ . A day later
395 (Fig. 8c-d), the domain is divided between thick and raining cumulus clouds and more widespread,
396 thinner stratocumulus clouds. At the time of RF07 (Fig. 8e-f), little stratocumulus cloud remains
397 near the inversion, and many isolated cumulus clouds are precipitating. The breakup of inversion
398 cloud is complete a day after RF07 (Fig. 8g-h), with many small cumulus clouds precipitating
399 across the domain that display little organization. This progression from nearly full cloud cover by
400 stratocumulus cloud to scattered cumulus clouds is echoed (at a much larger spatial scale) by the
401 GOES visible reflectance in Figs. 3b-e, which show the same times visualized in Figure 8.

402 The Lx29 simulation generally reproduces the observed transition along L06 Tr2.3 with modest
403 errors in MBL depth, thermodynamic profiles and TOA radiative fluxes. While larger errors are
404 seen at the time of RF07 in the vertical structure of clouds and precipitation, the aerosol environment
405 during RF07 was exceptionally clean and had strong vertical structure (Wood et al. 2018) and is
406 particularly challenging for a model using a prescribed and vertically-uniform N_d . As a result, we
407 suggest that Lx29 provides a credible simulation of L06 Tr2.3. In the following, the sensitivity of
408 L06 simulations to the effect of changes in domain size, N_d and the choice of trajectory (Table 1)
409 are evaluated using the Lx29 simulation as a reference.

410 *b. Domain size sensitivity*

411 The first sensitivity considered is to domain size. Two simulations, Lx29 and Lx10, are identically
412 configured except for the domain size: $L_x = L_y = 28.8$ km in Lx29 and $L_x = L_y = 9.6$ km in Lx10.
413 Both use the same horizontal grid spacing of 100 m. The domain-mean thermodynamic profiles
414 of Lx29 and Lx10 remain almost identical, as shown in Figures 5a-c and 7a-c, but the smaller
415 domain Lx10 has larger fractions of hydrometeors and drizzle/rain than the larger domain Lx29
416 at the times of both RF06 and RF07 (Figs. 5d-e and 7d-e). The intensity of rain is stronger in
417 the larger domain Lx29 at the time of RF06 (Figs. 5f), and precipitation onset occurs sooner in
418 the larger domain (Fig. 6f) as also found by previous studies (e.g., Vogel et al. 2016). While the
419 smaller domain Lx10 has a slightly larger cloud fraction during the day following RF06, the timing
420 of the cloudiness transition is similar in the two simulations.

421 These simulations of a strongly-forced stratocumulus-to-cumulus transition shows less sensitivity
422 to domain size than has been seen in simulations using steady forcings that allow cloud-radiative
423 interactions to play a larger role (e.g. Vogel et al. 2020).

424 *c. N_d sensitivity*

425 The sensitivity to different prescribed cloud droplet number concentrations N_d is much stronger
426 for this case than the sensitivity to domain size. Higher N_d leads to stronger cloud cover, a deeper
427 MBL, and delays in precipitation onset and the breakup of inversion cloud.

428 Despite strong nudging during the period before RF06, the cloud fraction varies systematically
429 with N_d from $\sim 90\%$ in Nd40 to $\sim 60\%$ in simulation Nd10.³ After RF06, the simulations develop
430 different boundary layer depths and structures, with Nd40 maintaining nearly full cloud cover for

³Note that all sensitivity studies for N_d used 9.6 km domains and should be compared with Lx10, which had a time-varying N_d from 40 cm^{-3} before and at the time of RF06 to 10 cm^{-3} at the time of RF07 and afterwards.

431 36 hours after RF06 and deepening substantially more than Lx10, whose cloud fraction fell below
432 50% in the hours following RF06 (Fig. 6a-b). Precipitation onset occurs first in Nd10, and the
433 accumulated precipitation is largest in that simulation despite having a smaller time-averaged LWP
434 than the other simulations (Fig. 6e-f). The ordering of MBL height with N_d is clearly visible
435 at the time of RF07 (Fig. 7a-c), with Nd40 having the deepest inversion. Unlike at the time of
436 RF06, the simulations with the smallest N_d have the largest hydrometeor and drizzle/rain fractions
437 (Fig. 7d-e). The Nd20 and Lx10 simulations show similar agreement with many observations, but
438 Nd20 biases in cloud fraction, TOA albedo, OLR and LWP are larger during the first two days of
439 the simulation, suggesting that the time-varying N_d used in Lx10 and Lx29 performs best among
440 the scenarios considered here (Fig. 6a,c,d,e).

441 We have seen that a single spatially-uniform value of N_d may not be realistic in precipitating
442 cumulus layers. While these simulations prescribed N_d because of the lack of observations of N_a
443 and N_d between the two research flights, simulations with prognostic droplet concentration and
444 aerosol schemes like those in Yamaguchi et al. (2017) and Berner et al. (2013) could be valuable
445 in future studies and help to test whether such schemes can reproduce the ultra-clean layers and
446 veil clouds observed during RF07 (Wood et al. 2018).

447 *d. Sensitivity to choice of trajectory (L06 Tr3.0)*

448 Simulations configured identically to Lx10, Nd10, Nd20 and Nd40 were also performed for
449 conditions along a second trajectory, Tr3.0, associated with the L06 case study as shown in Table 1.
450 The in situ sampling modules associated with Tr2.3 and Tr3.0 were adjacent in RF06. There
451 are modest differences between the simulations of Tr2.3 and Tr3.0. For example, the breakup of
452 cloud in the Lx10 simulation of Tr3.0 is delayed by ~16 hours as compared to GOES as shown in

453 Figure 9. However, the fidelity of the simulations and the sensitivity of cloud fraction and MBL
454 depth to N_d is similar in the two case studies.

455 *e. Summary*

456 The L06 case features large-scale ascent and clean conditions that promote MBL deepening,
457 precipitation and the breakup of inversion cloud between the two research flights, RF06 and RF07.
458 The reference simulation, Lx29 of L06 Tr2.3, captures the broad features of the transition, though
459 it struggles to reproduce the structure and intensity of precipitation in the very clean conditions
460 found during RF07. Sensitivity studies respond most strongly to changes in prescribed N_d , with
461 weaker sensitivity to domain size and the choice of trajectory (Tr2.3 vs. Tr3.0).

462 **4. Lagrangian case study L10 (RF10/RF11)**

463 Next we simulate a second contrasting Lagrangian case study, L10. It spans research flights
464 RF10 and RF11, which occurred on 27 and 29 July 2015, respectively. As described by Mohrmann
465 et al. (2019), this case displayed persistent cloud cover, slow deepening of the MBL and much
466 higher aerosol and cloud droplet number concentrations than seen in L06. All simulations of L10
467 use a time-varying prescribed N_d that decreases from 200 cm^{-3} at RF10 to 50 cm^{-3} at RF11 with
468 constant values before RF10 and after RF11 (Fig. 2f). As in L06, the simulations are nudged
469 strongly in the ~ 16 hours leading up to the first research flight, RF10 in this case.

470 The evolution of cloud cover along two neighboring trajectories, L10 Tr5.5 and L10 Tr6.0, is
471 shown in Figure 10, along with $12 \times 12^\circ$ images of GOES visible reflectance roughly every 24
472 hours along the trajectories. Consistent with the large-scale divergence seen in ERA5 (Fig. 1b),
473 the trajectories diverge with time, so that at the time of RF11 (Fig. 10d), Tr6.0 sits in a region
474 with mesoscale patches of inversion cloud, while Tr5.5 is in a broken cloud region. A day later

475 (Fig. 10e), inversion cloud has broken up around both trajectories, which are now separated by
476 over 700 km.

477 The large-scale forcings and relative humidity field along the two trajectories, L10 Tr5.5 and
478 Tr6.0, differ more strongly than the two L06 trajectories considered above (compare Fig. 11a-h
479 with Fig. 4a-h). The ERA5 inversion height increases abruptly along Tr5.5 due to large-scale cold
480 and moist advection, which is likely related to detrainment from nearby convection. Rahn and
481 Garreaud (2010) noted that such horizontal advection, which suggests the inversion of a different
482 inversion height from an upwind region, often explained large changes in inversion height in the
483 subtropical Southeast Pacific during the VOCALS field campaign. A moist layer appears above
484 the inversion in Tr5.5 approximately 12 hours before Tr6.0 (Fig. 11g-h). The ERA5 inversion
485 height along Tr6.0 deepens later and does not reach as high as along Tr5.5 (e.g., Fig. 11g-h).
486 Because the simulated inversion height (dashed line) lies above the ERA5 inversion (solid line),
487 large-scale horizontal advection that occurs above the inversion in ERA5 is applied within the
488 simulated boundary layer and has a significant influence on the evolution of the MBL in the LES.
489 For example, the cold and moist advection between hours 50 and 60 along Tr5.5 encourages the
490 deepening of the boundary layer beyond that implied by ERA5 (Fig. 4c,e,g). In addition, the thick
491 and persistent near-inversion stratocumulus cloud implies a relative humidity near 100%, which
492 is also moister than in ERA5 (Fig. 4g,i). Trajectory 6.0 experiences a similar period of cold and
493 moist advection following RF11, which is above the inversion in ERA5 but below the simulated
494 inversion height (Fig. 11d,f,h). Interestingly, both simulations finish with an approximately correct
495 inversion height despite quite different evolution in time: the simulations deepen gradually, while
496 ERA5 suggests a more abrupt deepening.

497 Next, a reference simulation, Lx86 for L10 Tr6.0, is now described in detail before the sensitivity
498 to domain size, horizontal grid spacing and choice of trajectory are explored.

499 *a. Reference L10 simulation: Lx86*

500 The reference L10 simulation, Lx86, uses a large domain $L_x = L_y = 86.4$ km and fairly coarse
501 horizontal grid spacing $\Delta x = \Delta y = 200$ m. The simulated boundary layer in Lx86 is initially
502 deeper and more decoupled than in L06 Tr2.3 (cf. Figs. 12a-c and 5a-c). The inversion height
503 and potential temperature profile closely match those of the downward flight leg (brown dots in
504 Fig. 12a), while the inversion height lies at the bottom edge of those observed in the mesoscale
505 region around the downward leg (grey shading). The ERA5 reanalysis θ is also consistent with
506 downward leg observations, though ERA5 is moister than the in situ measurements and all of the
507 simulations in the cloud layer (Fig. 12a-c). By construction, Lx86 better matches the mesoscale
508 average q_v and relative humidity profiles than those of the downward leg. Unlike in L06, the
509 observed winds are predicted well at the time of RF07 (Fig. S4a-b), and the surface sensible heat
510 flux is more biased than the latent heat flux (Fig. S5a-b). The vertical velocity variance also lies
511 within the range of observed values (Fig. S4c).

512 While the intensity of rainfall in Lx86 approximately matches the observations from the GV
513 HCR, the simulated rain fraction is much too small at all levels (Fig. 12e-f). As the hydrometeor
514 fraction in Lx86 is larger than retrieved from the GV lidar and radar in the upper part of the
515 cloud layer but smaller at lower levels, this suggests that the cloud in Lx86 is more extensive
516 and precipitates less than observed. We speculate that the simulations are less organized than the
517 observed cloud field, so the moistest columns in the simulations have smaller maximum LWP and
518 precipitate less readily.

519 While the GOES retrievals suggest nearly full cloud cover for a day following RF10, the inversion
520 cloud in Lx86 breaks up during the first day, leading to an underprediction of the GOES and CERES
521 TOA albedo during the day (Fig. 13a,c). The breakdown of the cloud cover on the following day is

522 also stronger than observed. Relative to GOES, the Lx86 median cloud top height is biased low at
523 the time of RF10, consistent with the over-estimation of OLR at that time (Fig. 13b,d). The OLR
524 in Lx86 lies closer to CERES, but exceeds it during most daytime hours on July 27-29. As in L06
525 (Fig. 6d), CERES and GOES OLR retrievals disagree for about a day along L10 Tr6.0 (Fig. 13d).
526 The diurnal cycle in GOES OLR appears to arise mainly from variations in cloud fraction, rather
527 than cloud top height (Fig. 13a,d). At the time of RF11 and afterwards, the cloud fraction and TOA
528 albedo are better predicted by Lx86, but the median cloud top height is biased high. After RF11,
529 the simulated OLR is biased low, suggesting some combination of too much inversion cloud and
530 a too deep MBL. The simulated LWP in Lx86 (Fig. 13e) is also smaller than GOES retrievals but
531 shows occasional agreement with SSMI retrievals, during the early morning hours of July 28 and
532 29 and during the period after RF11. Surface precipitation starts during the early morning hours
533 before RF11 and increases during the following night (Fig. 13f). Overall, precipitation plays a
534 lesser role in the MBL cloud evolution than in our earlier case L06.

535 At the time of RF11, the height of the simulated inversion in potential temperature from Lx86
536 matches GV in situ observations (Fig. 14a). However, the simulated cloud layer is colder than
537 observed and the Lx86 θ profile lacks the weak inversion at 2300 m in the observations. The
538 modeled q_v profile also lacks the moist layer between the two θ inversions at ~ 1900 and ~ 2300 m
539 (Fig. 14b). The mesoscale variations of humidity also suggest a moist layer above the strongest θ
540 inversion. ERA5 places in the inversion lower than observed and also lacks the above-inversion
541 moist layer seen in the observations (Fig. 14a-b). Within the lower part of the cloud layer between
542 about 1000 and 1500 m, the Lx86 relative humidity is on the lower edge of that observed in
543 the mesoscale region around Tr6.0 (Fig. 14c). The low bias in relative humidity in Lx86 is also
544 associated with too thin a cloud layer and too little cloud cover, as seen in profiles of hydrometeor
545 fraction in Figure 14d. The area fraction of drizzle/rain is also underpredicted within the cloud

546 layer but within the uncertainty of the observations at lower levels. The reflectivity associated with
547 that precipitation is overestimated in Lx86 at all levels, as compared to that retrieved from the GV
548 radar.

549 Figure 15a-b shows that mesoscale organization of cloud and precipitation in Lx86 has developed
550 during the spinup before RF10. We see four large patches of stratocumulus cloud with only weak
551 cold pools below the thicker cloud, suggesting drizzle and its subcloud evaporation are not yet
552 having much effect on the boundary-layer dynamics. On the following day (Fig. 15c-d), the
553 boundary layer has deepened and the inversion cloud has thinned. Several cumulus clouds rising
554 into the inversion cloud are precipitating, inducing cold pools near the surface. The inversion cloud
555 has partly broken up when RF11 passes the trajectory (Fig. 15e-f), though it later re-forms during
556 the night following RF11 (Fig. 13a). A day later, inversion clouds are mostly associated with active,
557 precipitating convection, and shallow convection is spread across the domain (Fig. 15g-h). The
558 onset of stronger precipitation during the night following RF11 (Fig. 13f) may contribute to the
559 breakup of inversion cloud in the simulations. In an observational study using satellite observations
560 along Lagrangian trajectories over subtropical low cloud regions, Eastman and Wood (2016) found
561 that, in deeper boundary layers, larger rain rates can facilitate the breakup of inversion cloud.

562 Simulating L10 has proven to be more challenging than L06. The Lx86 simulation of L10 Tr6.0
563 has significant biases in daytime cloud cover and precipitation and also lacks the observed moist
564 layer above the boundary layer at the time of RF11. However, the simulation does capture the
565 slower pace of the transition relative to L06 and the observed decrease in cloud cover on 30 July,
566 while also exhibiting only modest biases in MBL thermodynamic structure at the times of RF10
567 and RF11. Therefore, we will use Lx86 as a reference while studying the effects of domain size,
568 grid spacing and choice of trajectory (Tr5.5 vs. Tr6.0) on simulations of L10.

569 *b. Sensitivity to domain size and horizontal grid spacing*

570 Four simulations of L10 Tr6.0 were run using different combinations of domain size and hori-
571 zontal grid spacing. The grid and domain size for the Lx10 and Lx29 simulations were identical
572 to that in the L06 case study, with $\Delta x = \Delta y = 100$ m in domains of 9.6 and 28.8 km, respectively.
573 The other two simulations, Lx86 and Lx29D200, use a coarser $\Delta x = \Delta y = 200$ m in domains
574 with $L_x = L_y = 86.4$ and 28.8 km. While the results depend on both domain size and horizontal
575 grid spacing, these sensitivities will be presented together, using differences between Lx29 and
576 Lx29D200 to identify the sensitivity to horizontal grid spacing.

577 At the time of RF10, the thermodynamic profiles show little sensitivity to domain size and
578 grid spacing, though the largest domain Lx86 simulation has the lowest domain-average relative
579 humidity at cloud base and the lowest cloud base height, identified by the relative humidity
580 maximum at the top of the subcloud layer (Fig. 12a-c). Early in the simulations, the liquid water
581 path has a clear dependence on horizontal grid spacing, with the coarser Lx86 and Lx29D200
582 simulation having larger nighttime LWP during the spin-up period before RF10 (Fig. 13e). The
583 finer resolution simulations also show a dependence on domain size, with a larger LWP in Lx29
584 than Lx10.

585 The hydrometeor fraction profiles in Figure 12d also show a clear dependence on grid spacing.
586 The finer $\Delta x = \Delta y = 100$ m simulations, Lx10 and Lx29, have a deeper cloud layer than the coarser
587 simulations. This is unexpected since the LWP is smaller in finer grid simulations. It results from
588 a greater fraction of thin cloud near the stratocumulus cloud base. The simulations are grouped
589 differently when precipitation is considered. While the simulated rain fractions at the time of
590 RF10 are much smaller than observed (Fig. 12e), rain occurs more frequently in the largest domain
591 Lx86 simulation and in Lx29. These simulations also show earlier precipitation onset and larger

592 accumulated precipitation in Figure 13f. It is notable that Lx29 precipitates earlier and more
593 than Lx29D00 despite having a smaller mean LWP before RF10. This result is consistent with
594 Seifert and Heus (2013), who found that precipitation onset and organization of the humidity field
595 proceed faster in finer grid simulations in a precipitating shallow cumulus cloud field. The latest
596 precipitation onset occurs in the smallest-domain simulation, Lx10.

597 The regulation of inversion height by surface precipitation (e.g., Albrecht 1993) is visible in
598 the modeled inversion heights at the time of RF11 in Figure 14a-c and in the cloud-layer vertical
599 velocity variance in Figure S6c. Lx86, the simulation with the greatest accumulated precipitation at
600 that time (Fig. 13f), has the lowest inversion height and the closest to the observed inversion height,
601 while the simulation with the least precipitation, Lx10, has the deepest and most biased inversion
602 height. Lx10 is the only simulation whose hydrometeor fraction lies within the uncertainty of
603 the GV observations (Fig. 12d). While all simulations match the rain fraction within uncertainty
604 below the cloud layer and underestimate it within the cloud layer, the intensity of rain within the
605 cloud layer increases with domain size, and all simulations overestimate the observed rain intensity
606 (Fig. 14e-f). Following RF11, cloud fraction increases in all of the simulations before falling
607 in Lx29 and Lx86 during the morning of 30 July (UTC). This cloud breakup does not occur in
608 Lx29D200 and Lx10, suggesting that the increased precipitation in Lx29 and Lx86 facilitates the
609 transition. As mentioned above, the impact of precipitation on cloud breakup in deeper boundary
610 layers was noted by Eastman and Wood (2016) based on remote sensing observations of subtropical
611 cloud transitions.

612 Despite a wide range of domain sizes and two choices of grid spacing, the domain-mean
613 properties of the simulations show modest sensitivities until late in the simulations. Precipitation
614 onset occurs sooner in the largest domain simulation and in the higher resolution simulation with

615 $L_x = L_y = 28.8$ km. The inversion cloud breaks up on the last day only in these two simulations,
616 so that the timing of the transition in cloudiness may vary with domain size and grid spacing.

617 *c. Sensitivity to choice of trajectory (L10 Tr5.5)*

618 A second trajectory associated with this Lagrangian case study, L10 Tr5.5, was also simulated
619 in a configuration identical to the Lx10 simulation of L10 Tr6.0 discussed above. Observations
620 of this pair of trajectories show noticeable differences even at the time of the first research flight,
621 RF10. The boundary layer is more strongly decoupled for Tr6.0 than Tr5.5, and Tr5.5 has more
622 extensive cloud cover, as inferred from the hydrometeor fraction (not shown). A comparison of the
623 two trajectories in Figure 10b shows that at the time of RF10, Tr5.5 sits near the center of a broad
624 region of cloud cover while Tr6.0 is closer to the edge. Nearly full cloud cover is nevertheless
625 maintained in GOES observations within two degrees of the Tr6.0 trajectory through the day
626 following RF10 (Fig. 13a).

627 Between RF10 and RF11, the trajectories diverge strongly, and at the time of RF11, the two tra-
628 jectories sit in quite different cloud fields: broken cloud around Tr5.5 and patches of stratocumulus
629 around Tr6.0 (Fig. 10d). The observed boundary layer is deeper in Tr5.5 and has moist layers and
630 hydrometeors present below two inversions, at about 1700 and 3200 m (Fig. 16d). In the region
631 around Tr6.0, no hydrometeors were observed above 2100 m, though a moist layer was present
632 below a second inversion at 2300 m, possibly as a result of detrainment from nearby convection
633 (Fig. 14b-c). The simulation of L10 Tr5.5 fails to reproduce the two inversions in the observed
634 sounding, instead producing a single inversion at 3000 m atop a deep, decoupled MBL capped
635 by stratocumulus cloud (Fig. 16a-d). These temperature and moisture profiles resemble the ERA5
636 soundings more closely than the GV in situ measurements, though the simulations are colder and
637 moister in the upper part of the MBL than ERA5 (Fig. 16a-b).

638 As all simulations in this paper are forced by large-scale vertical motion and horizontal advective
639 tendencies from ERA5 (see Fig. 11) that have been extracted along these Lagrangian trajectories,
640 they may have difficulty capturing features — such as the above-inversion moist layers during RF11
641 (Fig. 14a, 16a) — if those features are not captured by ERA5. However, some of the biases present
642 in the simulation of Tr5.5 at the time of RF11 are not related to ERA5. For example, the prominent
643 cold and moist bias in the simulations between 2 and 3 km altitude likely results from the persistence
644 of a stratocumulus layer below a very deep inversion in this case, while the observations suggest
645 the breakup of cloud above these heights. LES domains smaller than hundreds of kilometers may
646 have difficulty capturing features like these that are generated by convection and clouds scattered
647 across a region.

648 Simulations along the two trajectories of Lagrangian case L10 differ much more in their evolution
649 and fidelity than was found in L06. The divergence of the trajectories leads to them being influenced
650 by nearby convection and moist layers aloft at different times. The simulation of L10 Tr5.5 is
651 particularly challenging at the time of RF11, leading to much larger biases than seen in simulations
652 of L10 Tr6.0.

653 *d. Summary*

654 The L10 case study is marked by higher aerosol concentrations than L06, along with persistent
655 subsidence and the associated divergence of the two trajectories over time. Large-scale horizontal
656 advection and moist layers — possibly associated with nearby convection — promote MBL deep-
657 ening later in the case study, following a period of nearly steady MBL depth in ERA during roughly
658 the first two days following RF10. While simulations of the L10 case study reproduce the observed
659 thermodynamic structure of the MBL at the time of RF10 and also the MBL depth of ERA5 at the
660 end of the simulations, larger biases in cloud cover and MBL depth occur in between. Daytime

661 cloud cover is underestimated earlier in the transition and is overestimated later along the two
662 trajectories, especially in smaller domains. The above-inversion moist layers, which occur during
663 the latter part of L10, are not represented well in either the simulations or the ERA5 reanalysis that
664 supplied the large-scale forcings for the LES. The sensitivity of L10 Tr6.0 simulations to changes
665 in domain size and horizontal grid spacing is modest before the final day of the simulation. Larger
666 domains and higher resolution precipitate sooner, as suggested by the work of Seifert and Heus
667 (2013) and Vogel et al. (2016), but the changes in marine boundary layer (MBL) structure and
668 depth are limited. In L10 Tr6.0, inversion cloud breakup occurs sooner in the two runs with the
669 largest amount of precipitation, including the one in the largest domain ($L_x = L_y = 86.4$ km).

670 **5. Effects of Subsidence and N_d on L06 and L10**

671 The simulations of L06 and L10 capture the observed difference in the pace of the transition,
672 with the breakup of clouds occurring 1-2 days earlier along L06. Mohrmann et al. (2019) attributed
673 the slower transition in L10 to enhanced subsidence, weaker surface fluxes and later precipitation
674 onset due to higher aerosol and cloud droplet concentration when compared to L06. Here, three
675 additional sensitivity studies, all in 9.6 km square domains, evaluate the individual contributions
676 of subsidence and cloud droplet number concentration, N_d , in facilitating the transition.

677 Along trajectory L06 Tr2.3, simulation L10Omega is configured identically to Lx10, except that
678 its large-scale vertical motion, w_{LS} , includes a time-constant but vertically-varying offset equal to
679 the difference in w_{LS} between L10 Tr6.0 and L06 Tr2.3 when averaged from t_1 (the time of the
680 first research flight) to the end of each simulation. In L06 Tr2.3, the stronger subsidence induces
681 a slightly shallower cloud top, thinner cloud, and slightly earlier cloud breakup (by ~8 hours)
682 in L10Omega (Fig. 17). This result is consistent with Van der Dussen et al. (2016), who found
683 that weaker subsidence delayed cloud breakup in idealized simulations of ASTEX. A separate

684 simulation, Nd200, tests the use of a larger and constant $N_d = 200 \text{ cm}^{-3}$ in L06 Tr2.3 that is
685 characteristic of L10 at the time of the first research flight, RF10. This simulation breaks up later
686 than Lx10, but only a couple of hours later than simulation Nd40 (Fig. 17), which maintained
687 $N_d = 40 \text{ cm}^{-3}$ throughout L06 Tr2.3. The similar timing of the cloud transitions in Nd40 and
688 Nd200 may result in part from the limited ability of additional aerosols to suppress precipitation
689 in deep boundary layers where the cores of cumulus clouds have increasingly large liquid water
690 content near cloud top.

691 One further sensitivity study, Nd40-10, was performed in L10 Tr6.0 and prescribed that N_d
692 decreases from 40 cm^{-3} at the time of RF10 to 10 cm^{-3} at the time of RF11, as in the reference
693 simulation of L06. This represents a decrease of N_d by a factor of five from the other L10
694 Tr6.0 simulations. While the smaller N_d in simulation Nd40-10 leads to an immediate onset of
695 precipitation during the spinup phase of the simulation, cloud breakup occurs approximately 60
696 hours later (Fig. 18). Still, simulation Lx10, with fivefold larger N_d , has nearly full cloud cover a day
697 later at the end of the simulation. In addition, Nd40-10 experiences little deepening of the boundary
698 layer following RF11 as compared to more than a kilometer of deepening in Lx10 following RF11
699 (Fig. 18b). While specifying a low value of N_d in a boundary layer with a much larger observed N_d
700 may be artificial, it does illustrate the role that precipitation can play in facilitating cloud breakup
701 and regulating boundary layer depth.

702 These sensitivity studies suggest that, after the onset of precipitation, it is a stronger control on the
703 breakup of inversion cloud than subsidence. However, subsidence does help control precipitation
704 onset through the regulation of MBL depth and, thereby, liquid water path.

6. Conclusions

The goal of this study has been to simulate two Lagrangian case studies from the CSET field campaign and evaluate the fidelity of these simulations against a comprehensive set of in situ and remote sensing observations from the GV aircraft and satellite datasets, along with reanalysis. The large eddy simulations perform well in general, though there are differences with observations, particularly in the area fraction and intensity of precipitation. Each Lagrangian case study includes two neighboring trajectories, so that the sensitivity of the simulated transition to spatial variability in forcings can be explored.

The simulations capture the difference in the pace of the transition between L06 and L10 but struggle with some details of the L10 case study with too little daytime cloud cover early in the simulation and a high bias in cloud top height later in the simulation. The L10 simulations also struggle with the representation of moist layers above the inversion at the time of RF11, which are not always captured in the forcings derived from ERA5.

In both the L06 and L10 case studies, changes in prescribed cloud droplet number concentration N_d have a substantial impact on the MBL depth and decoupling along with the cloud cover for simulations. L06 simulations with the lowest $N_d = 10 \text{ cm}^{-3}$ cannot maintain the observed full cloud cover even when the domain-mean profiles are nudged towards observations. The transition in L06 is delayed and the MBL over-deepens when N_d is fixed to 40 or 200 cm^{-3} . Our simulations do not account for vertical gradients observed in strongly precipitating cumulus cloud layers of N_a and N_d such as seen in Figure 2, which have been attributed by aerosol removal by precipitation (Wood et al. 2018) and may better be represented in aerosol-coupled LES. Even if the sensitivity to N_d is overestimated in our simulations, the results of Yamaguchi et al. (2017) — which included simulations with an aerosol-coupled LES — also suggest a strong relationship between cloud

728 fraction and N_d in sensitivity studies of a single, idealized transition case that is not visible across
729 across a broader set of observed cases in CSET (Bretherton et al. 2019).

730 This discrepancy between the simulated sensitivity of cloudiness to N_d in modeling case studies
731 (in this study and Yamaguchi et al. 2017) and the observed lack of correlation between cloudiness
732 and N_d in observations after accounting for EIS (Bretherton et al. 2019) could reflect the longstand-
733 ing difficulty of disentangling aerosol impacts from meteorological variability (e.g., Brenguier et al.
734 2003). However, the aerosol concentrations within an air mass may reflect the aerosol sources
735 and sinks experienced over its history, including surface fluxes, entrainment of free tropospheric
736 aerosol and collision-coalescence scavenging by precipitation (e.g., Wood et al. 2017). Freely
737 changing N_a or N_d in sensitivity studies might lead an air mass to have aerosol concentrations
738 inconsistent with its history of aerosol sources and sinks and induce changes in cloudiness that are
739 unlikely to be observed. The simulations of cloud transitions in the Northeast Pacific by McGibbon
740 and Bretherton (2017) may provide some valuable context. Simulations of several observed case
741 studies during the MAGIC field campaign showed no correlation between N_d and cloud fraction
742 after accounting for the effect of EIS on cloud fraction. While sensitivity studies that doubled N_d in
743 each case study did not have an appreciable effect on cloud fraction, the increase in N_d did lead to
744 modest increases in liquid water path and cloud albedo. In addition, the simulations of McGibbon
745 and Bretherton (2017) couple their LES to the large-scale circulation using a weak temperature
746 gradient approach that models the interaction of the doubly-periodic domain with the surrounding
747 mesoscale region. In contrast, our simulations do not include such feedbacks, which might limit
748 changes in MBL depth and cloud thickness when compared to the simulations here.

749 While the ERA5 reanalysis generally performs well here, biases in ERA5 cloud layer humidity
750 show the value of in situ and remote sensing observations from platforms like the GV. How-
751 ever, given the expense and sparsity of such observations, combining well-constrained reanalysis

752 with remote sensing data products at high spatial resolution makes possible the generation of
753 many Lagrangian case studies across the subtropical oceans that include significant observational
754 constraints, building on the approach in Sandu et al. (2010). In particular, observations of top-of-
755 atmosphere longwave and shortwave radiative fluxes provide a significant test of the simulations,
756 providing information about boundary layer depth, cloud cover and cloud thickness. Further data
757 products, including microwave satellite observations of total water path and cloud water path also
758 provide rich information about the organization of cloud and water vapor within subtropical MBLs.
759 Such Lagrangian case studies hold promise for understanding aerosol-cloud interactions induced
760 by aerosol perturbations associated with ships, the organization of shallow cumulus convection
761 as observed during EUREC4A (Bony et al. 2017) and even mixed-phase stratocumulus clouds
762 in the Arctic (Neggers et al. 2019). While it can be expensive to simulate multiple instances of
763 Lagrangian case studies, we would advocate for the development of multiple trajectories associated
764 with each Lagrangian case study to evaluate the consistency of the forcings across space and time
765 and the representation of the transition in simulations of neighboring air masses.

766 *Data availability statement.* Data and MATLAB scripts required to reproduce the plots in the
767 paper, along with further information from the simulations is available here: [https://doi.org/](https://doi.org/10.5281/zenodo.4057106)
768 [10.5281/zenodo.4057106](https://doi.org/10.5281/zenodo.4057106). Data have been provided by NCAR/EOL under the sponsorship of
769 the National Science Foundation and can be found at [https://data.eol.ucar.edu/field_](https://data.eol.ucar.edu/field_projects/cset)
770 [projects/cset](https://data.eol.ucar.edu/field_projects/cset). The MW+IR OI SST, used in Figures 3 and 10, are produced by Remote Sensing
771 Systems, sponsored by NASA, and available at <http://www.remss.com/>. SSM/I and SSMIS data
772 are produced by Remote Sensing Systems. Data are available at www.remss.com/missions/ssmi.
773 CERES SYN1deg Ed4A data were obtained from the NASA Langley Research Center Atmospheric
774 Science Data Center.

937 **LIST OF TABLES**

938 **Table 1.** Description of simulations for L06 and L10 Lagrangian case studies. The two
939 values of N_d give the cloud droplet number concentration at t_1 , the passage
940 of westward reseach flight (RF06 for the L06 case study and RF10 for L10),
941 and t_2 , the passage of the eastward research flight, RF07 or RF11, two days
942 later. These two times, along with the start time of the simulation, t_0 , are
943 given beneath the name of each trajectory. While some simulations are used for
944 multiple cases and trajectories, the meaning should be clear from the context.
945 The simulations will also be introduced with the case and trajectory number,
946 e.g., L06 Tr2.3 Lx29. 45

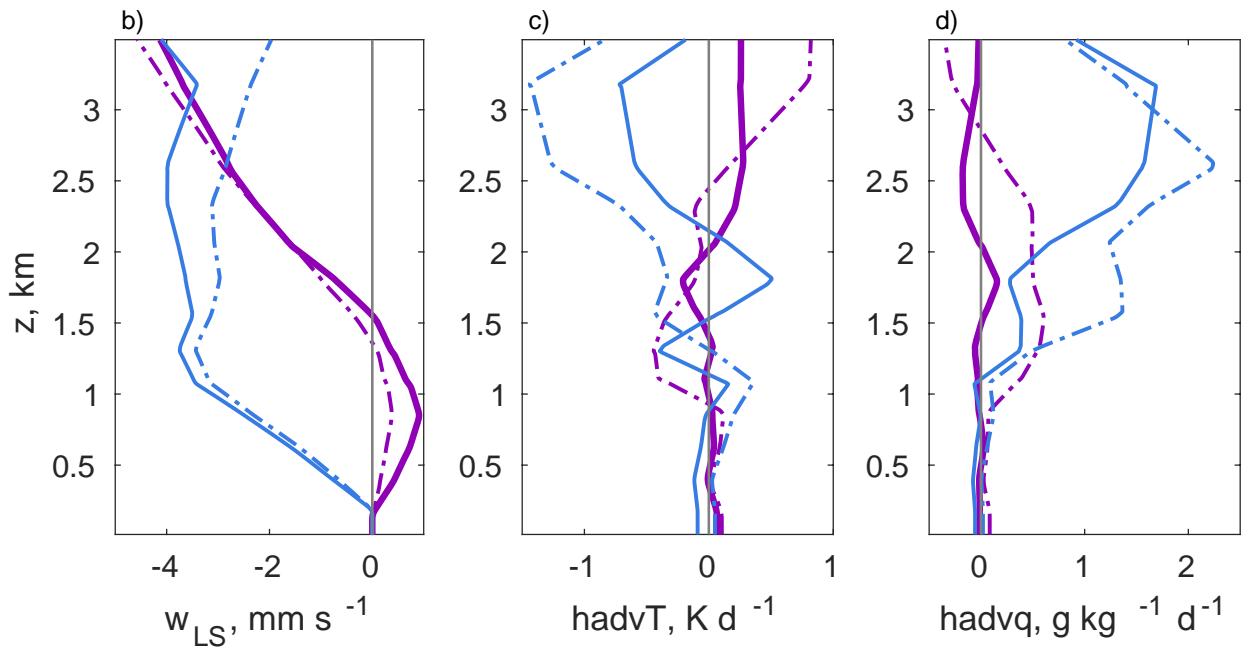

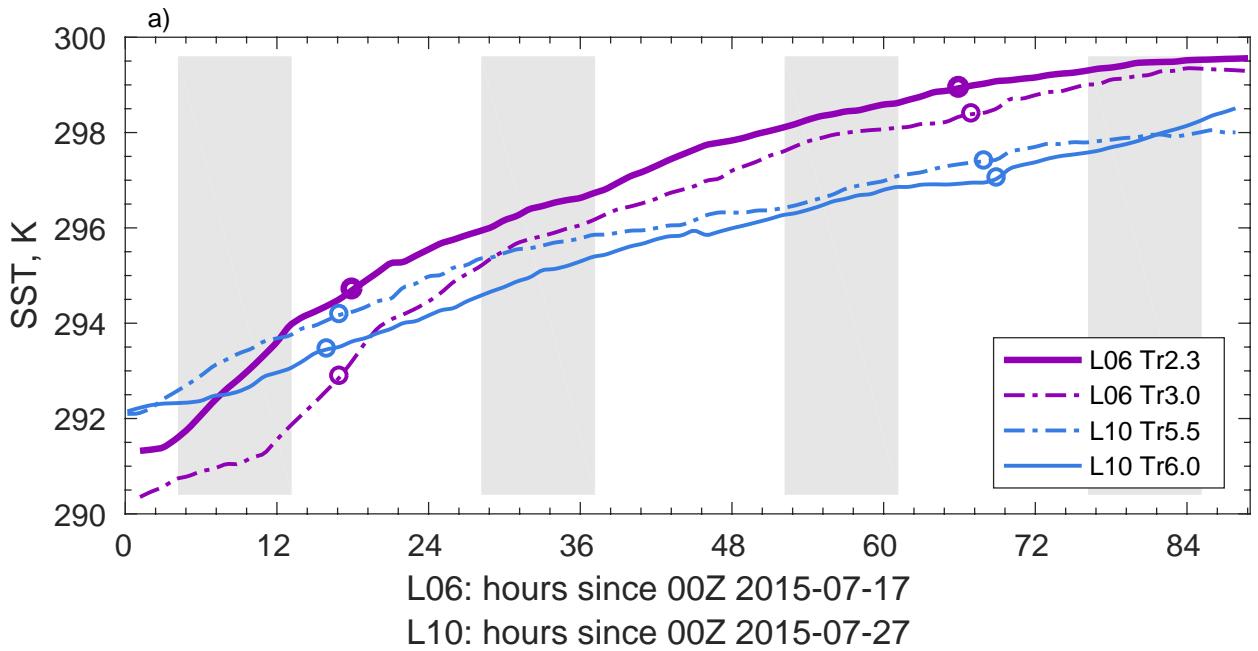

947 TABLE 1. Description of simulations for L06 and L10 Lagrangian case studies. The two values of N_d give the
 948 cloud droplet number concentration at t_1 , the passage of westward reseach flight (RF06 for the L06 case study
 949 and RF10 for L10), and t_2 , the passage of the eastward research flight, RF07 or RF11, two days later. These
 950 two times, along with the start time of the simulation, t_0 , are given beneath the name of each trajectory. While
 951 some simulations are used for multiple cases and trajectories, the meaning should be clear from the context. The
 952 simulations will also be introduced with the case and trajectory number, e.g., L06 Tr2.3 Lx29.

Case	Trajectory	Name	$L_x = L_y$ (km)	$\Delta x = \Delta y$ (m)	$N_d(t_1)$ (cm^{-3})	$N_d(t_2)$ (cm^{-3})
L06	Tr2.3 $t_0 = 17 \text{ Jul } 01\text{Z}$ $t_1 = 17 \text{ Jul } 18\text{Z}$ $t_2 = 19 \text{ Jul } 18\text{Z}$	Lx29	28.8 km	100 m	40	10
		Lx10	9.6 km	100 m	40	10

LIST OF FIGURES

953		
954	Fig. 1.	LES forcings. (a) SST along the trajectory (with circles indicating the sampling times on the westward and eastward flights). (b-d) Profiles of large-scale vertical motion w_{LS} , horizontal temperature advection hadvT and horizontal moisture advection hadvq , all relative to the moving air column and time-averaged between the two flights. 48
955		
956		
957		
958	Fig. 2.	Top two rows: In situ observations of accumulation mode aerosol N_a from the GV UHSAS instrument (blue symbols, line and shading) and cloud droplet number concentrations N_d from the GV CDP (red symbols, line and shading) for a) RF06 Tr2.3, b) RF07 Tr2.3, d) RF10 Tr6.0, e) RF11 Tr6.0. Observations from the downward flight leg when the GV was closest to this trajectory are shown using red +s for N_d and blue dots for N_a . The range of in situ observations in the mesoscale region within 2.5° around the downward flight leg are shown with dark and light shading (25-75 and 5-95 percentiles, respectively). The mean profile in this mesoscale region (GVMeso in the legend) is shown by the circular symbols and the line connecting them. At bottom, N_d retrievals from GOES and prescribed N_d for simulations for c) L06 Tr2.3 and f) L10 Tr6.0. In this and other plots of GOES retrievals, the gray shading shows an estimate of the spatial uncertainty of the retrieval: the range of the median N_d retrievals in five $2 \times 2^\circ$ boxes, one centered on the trajectory and four overlapping $2 \times 2^\circ$ boxes to the northwest, northeast, southwest and southwest of the trajectory. The diurnal cycle is shown using the light gray boxes, which indicate night-time periods during the simulation. 49

1022	with simulations Lx10 and Nd40.	64
1023	Fig. 18. As in figure 6 but comparing the L10 Tr6.0 sensitivity study L06Nd with simulation Lx10.	65

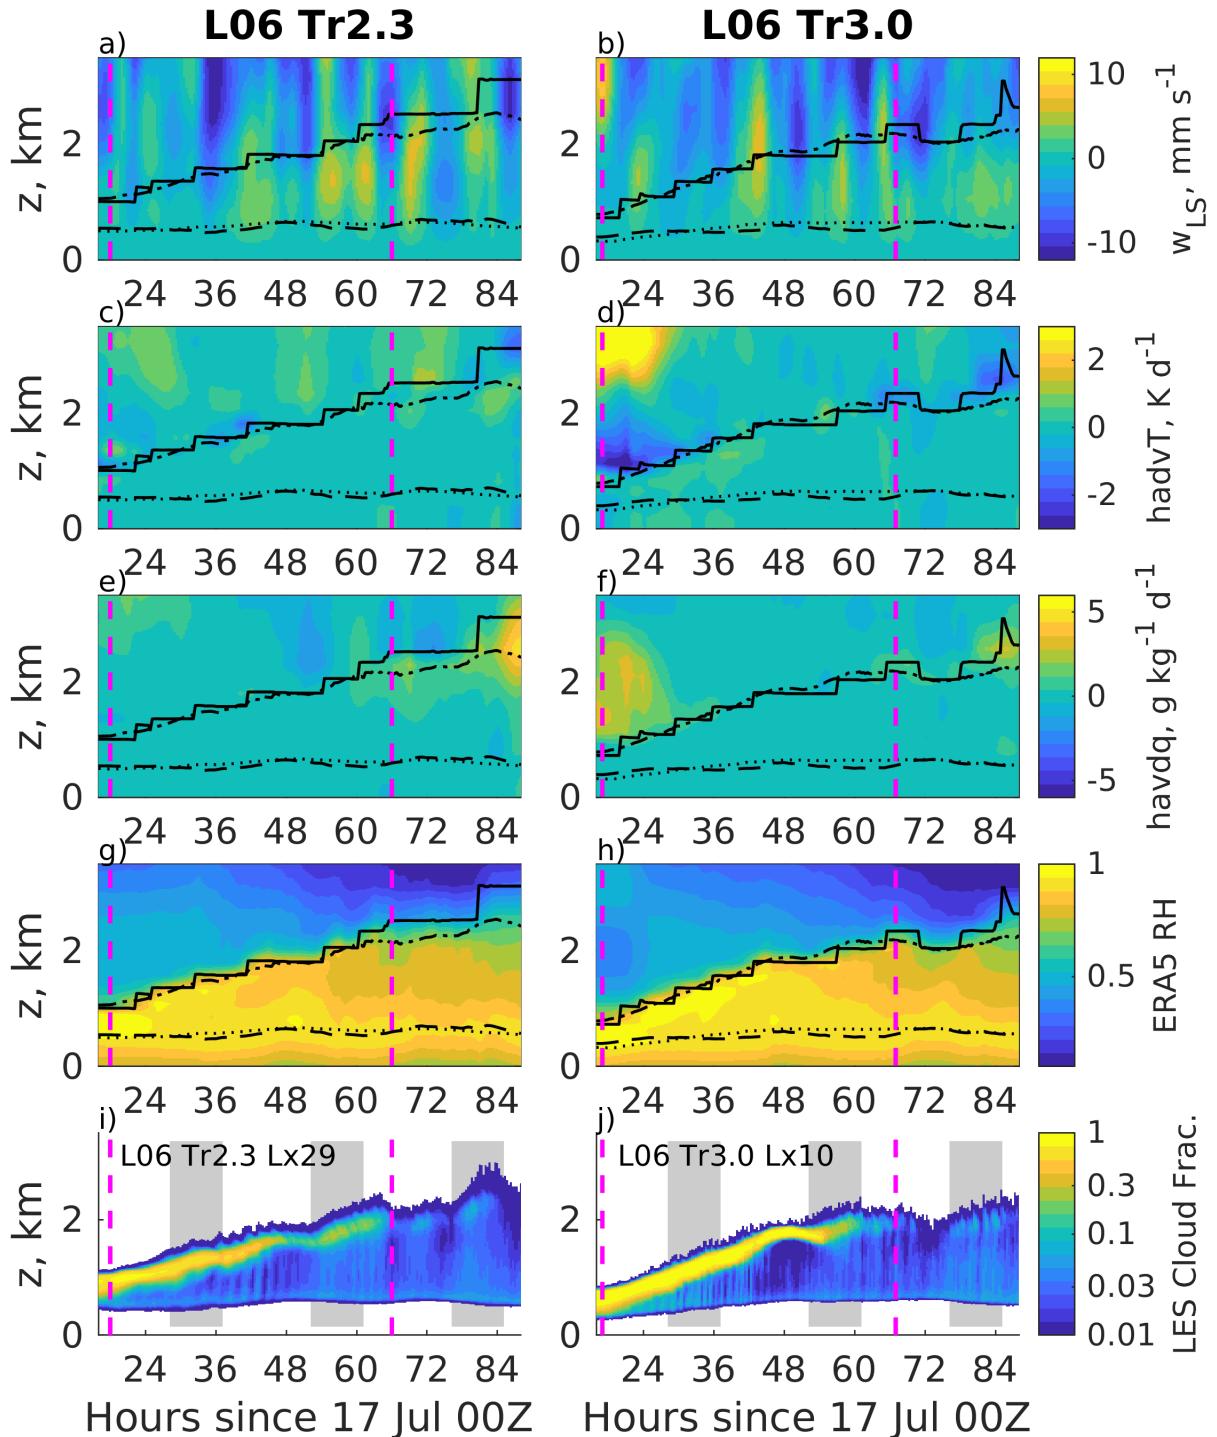

1024 FIG. 1. LES forcings. (a) SST along the trajectory (with circles indicating the sampling times on the westward
 1025 and eastward flights). (b-d) Profiles of large-scale vertical motion w_{LS} , horizontal temperature advection $hadvT$
 1026 and horizontal moisture advection $hadvq$, all relative to the moving air column and time-averaged between the
 1027 two flights.

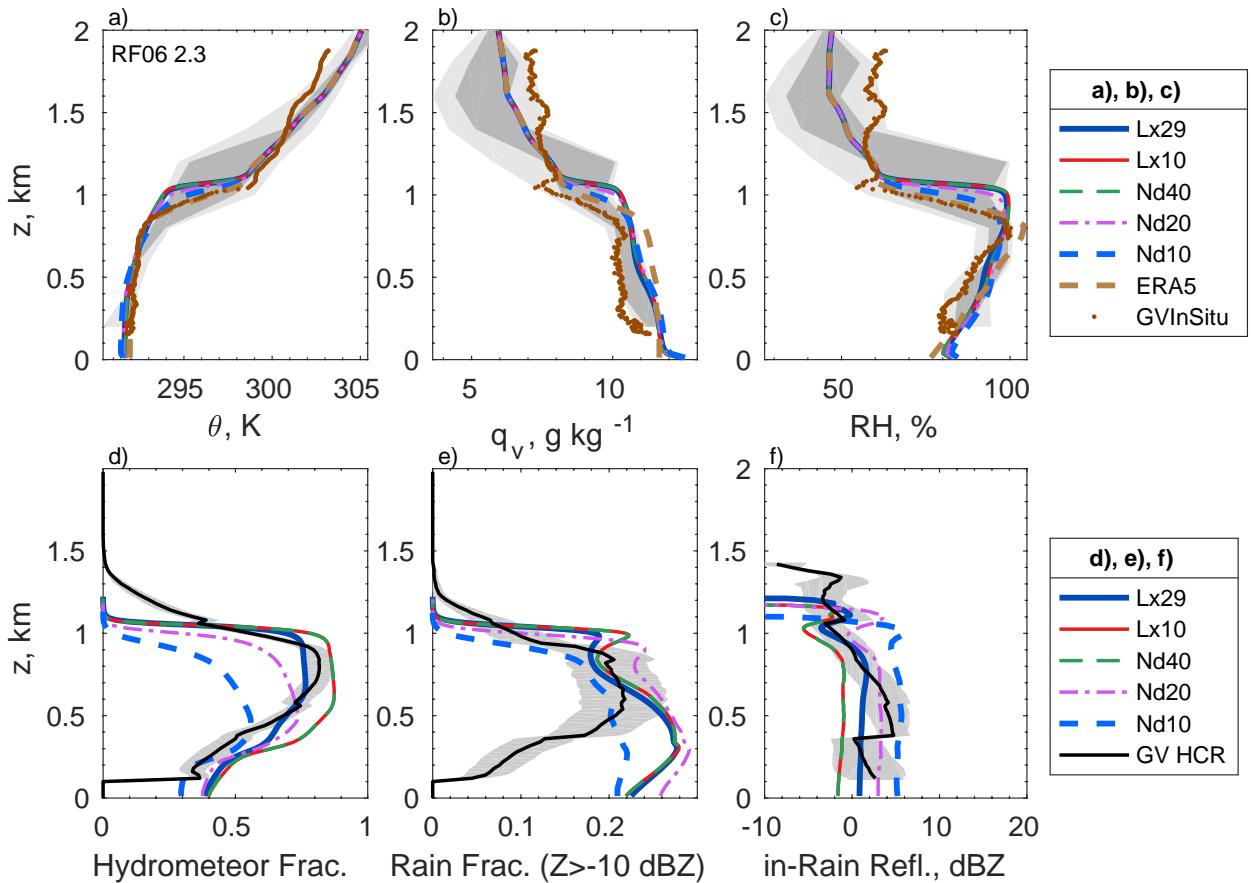

1028 FIG. 2. Top two rows: In situ observations of accumulation mode aerosol N_a from the GV UHSAS instrument
 1029 (blue symbols, line and shading) and cloud droplet number concentrations N_d from the GV CDP (red symbols,
 1030 line and shading) for a) RF06 Tr2.3, b) RF07 Tr2.3, d) RF10 Tr6.0, e) RF11 Tr6.0. Observations from the
 1031 downward flight leg when the GV was closest to this trajectory are shown using red +s for N_d and blue dots for
 1032 N_a . The range of in situ observations in the mesoscale region within 2.5° around the downward flight leg are
 1033 shown with dark and light shading (25-75 and 5-95 percentiles, respectively). The mean profile in this mesoscale
 1034 region (GVMeso in the legend) is shown by the circular symbols and the line connecting them. At bottom, N_d
 1035 retrievals from GOES and prescribed N_d for simulations for c) L06 Tr2.3 and f) L10 Tr6.0. In this and other
 1036 plots of GOES retrievals, the gray shading shows an estimate of the spatial uncertainty of the retrieval: the range
 1037 of the median N_d retrievals in five $2 \times 2^\circ$ boxes, one centered on the trajectory and four overlapping $2 \times 2^\circ$ boxes

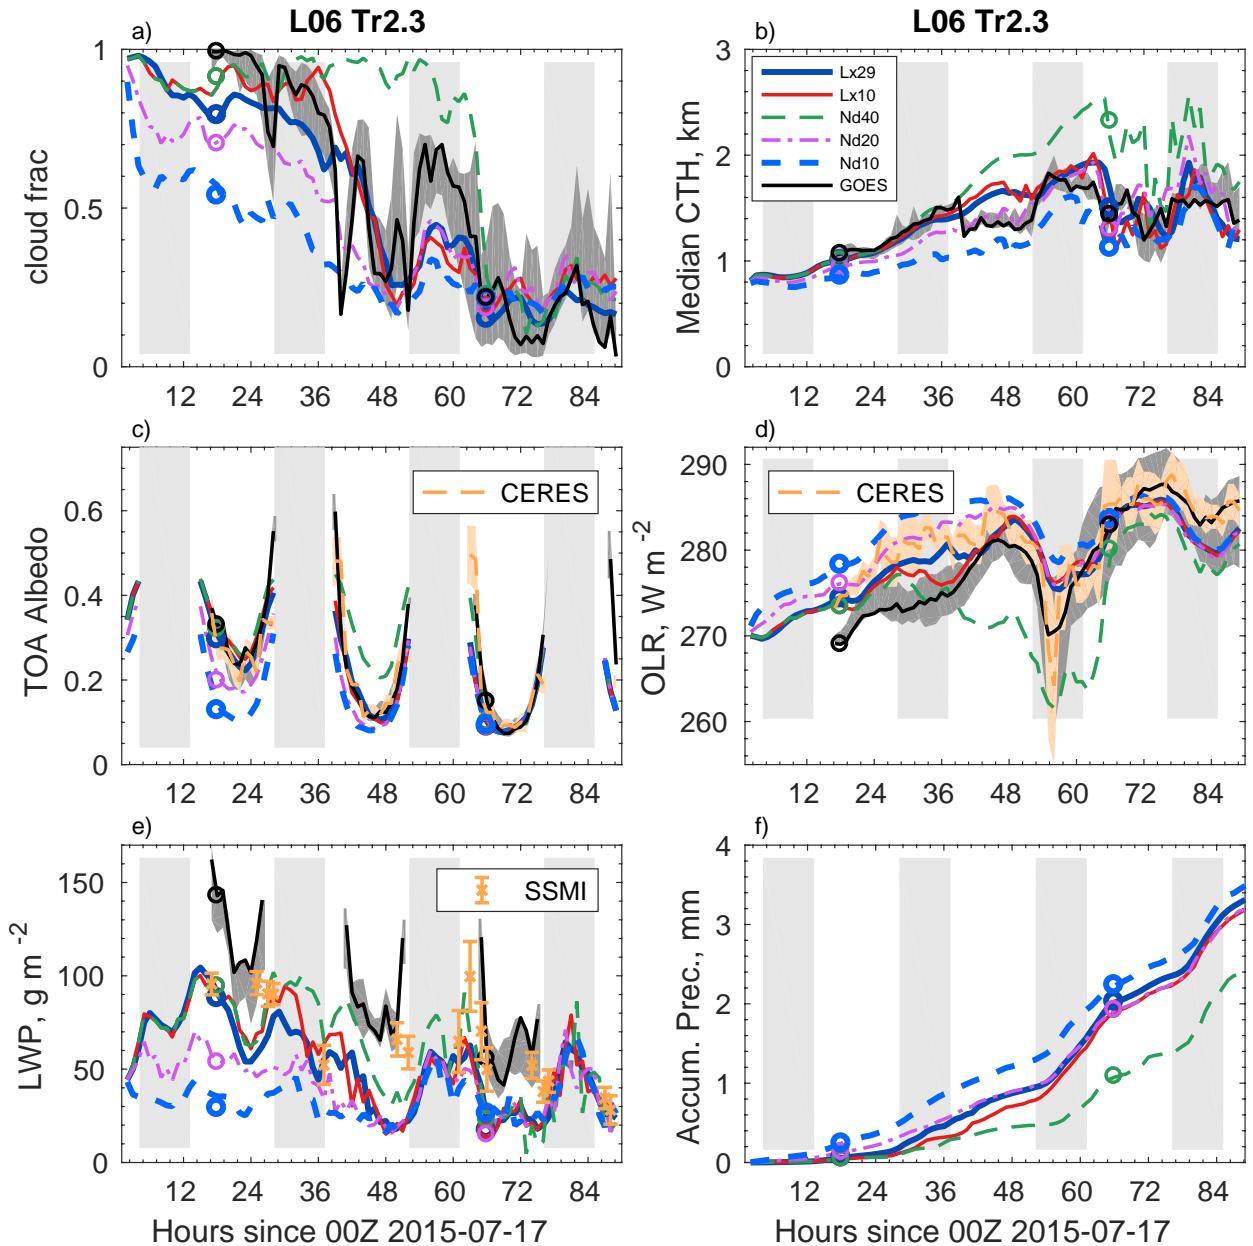

1040 FIG. 3. a) Trajectories and flight paths for the L06 Lagrangian case study. The filled symbols show the
 1041 evolution of cloud cover along the trajectory, and the flight paths are solid where they intersect the trajectories
 1042 L06 Tr2.3 and L06 Tr3.0. Contours show sea surface temperature at 12Z on 17 July, three hours before RF06
 1043 took off. b-e) GOES visible reflectance at the times indicated by the bold squares/diamonds in a).

1044 FIG. 4. Time-height profiles of large-scale forcings from ERA5 for trajectories L06 Tr2.3 (panels a,c,e,g)
 1045 and L06 Tr3.0 (panels b,d,f,h): a,b) large-scale vertical velocity w_{LS} , large-scale horizontal advection of c,d)
 1046 temperature and e,f) moisture, and g,h) ERA5 relative humidity. In i,j), time-height profiles of cloud fraction
 1047 from L06 Tr2.3 simulation Lx29 and L06 Tr3.0 simulation Lx10. The magenta lines marks the times of the two
 1048 research flights, RF06 and RF07. The inversion heights of ERA5 and of the representative simulation are shown
 1049 in Fig. 4a-h by the solid and dash-dotted lines, respectively.

1050 FIG. 5. For RF06 passage of Trajectory 2.3 on 17 July 2015, profiles of simulated and observed a) potential
 1051 temperature, b) water vapor mass mixing ratio, c) relative humidity, d) hydrometeor fraction, e) rain fraction
 1052 (including drizzle) based on a -10 dBZ threshold, and f) radar reflectivity averaged over points with > -10 dBZ.
 1053 In a-c), ERA5 reanalysis values are shown by the dashed light brown line, along with in situ measurements by
 1054 the GV aircraft during the downward flight leg (brown dots) and within 2.5 ° of the downward leg (light shading
 1055 indicates the 5-95% range and dark shading the 25-75% range). In panels d-f), the observations are derived
 1056 from (d) the combined radar-lidar cloud mask and (e-f) the GV HIAPER Cloud Radar (HCR). The simulated
 1057 hydrometeor fraction is based on a threshold of -40 dBZ. In d-f), the grey shading shows two standard errors
 1058 around the mean observed value for each quantity.

1059 FIG. 6. Time series of (a) cloud fraction, (b) median cloud top height (CTH), (c) top-of-atmosphere (TOA)
 1060 albedo, (d) TOA outgoing longwave radiation, (e) liquid water path and (f) accumulated surface precipitation
 1061 along L06 trajectory T2.3 from simulations and retrievals from GOES (a-e), CERES (c-d) and SSMI (e).
 1062 Retrievals of surface precipitation are not available, and the shaded uncertainty ranges are calculated as described
 1063 in section 2a. Simulated CTH is the mean height in cloudy columns where the cloud water path reaches 20 g
 1064 m^{-2} . Circles indicate values at the times of the two research flights.

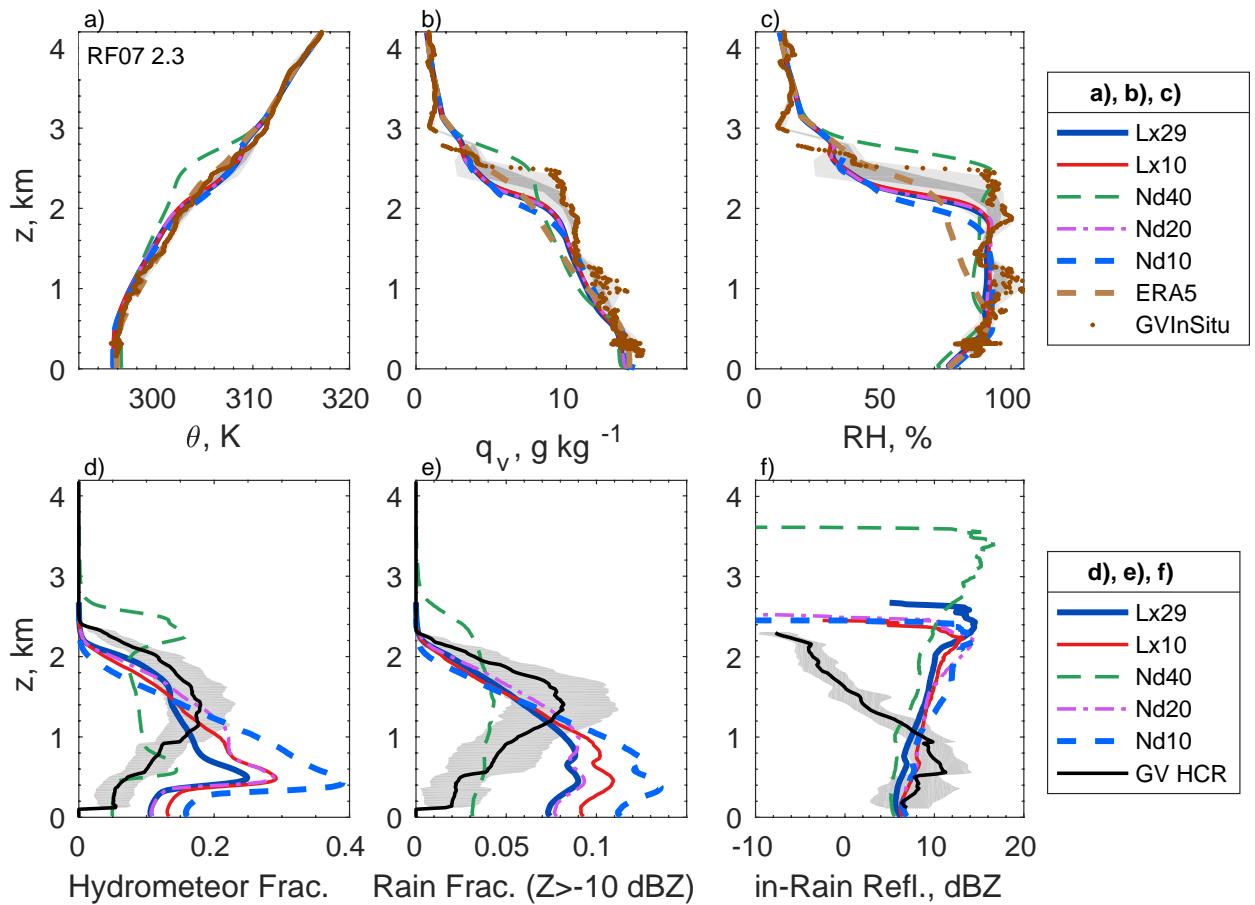

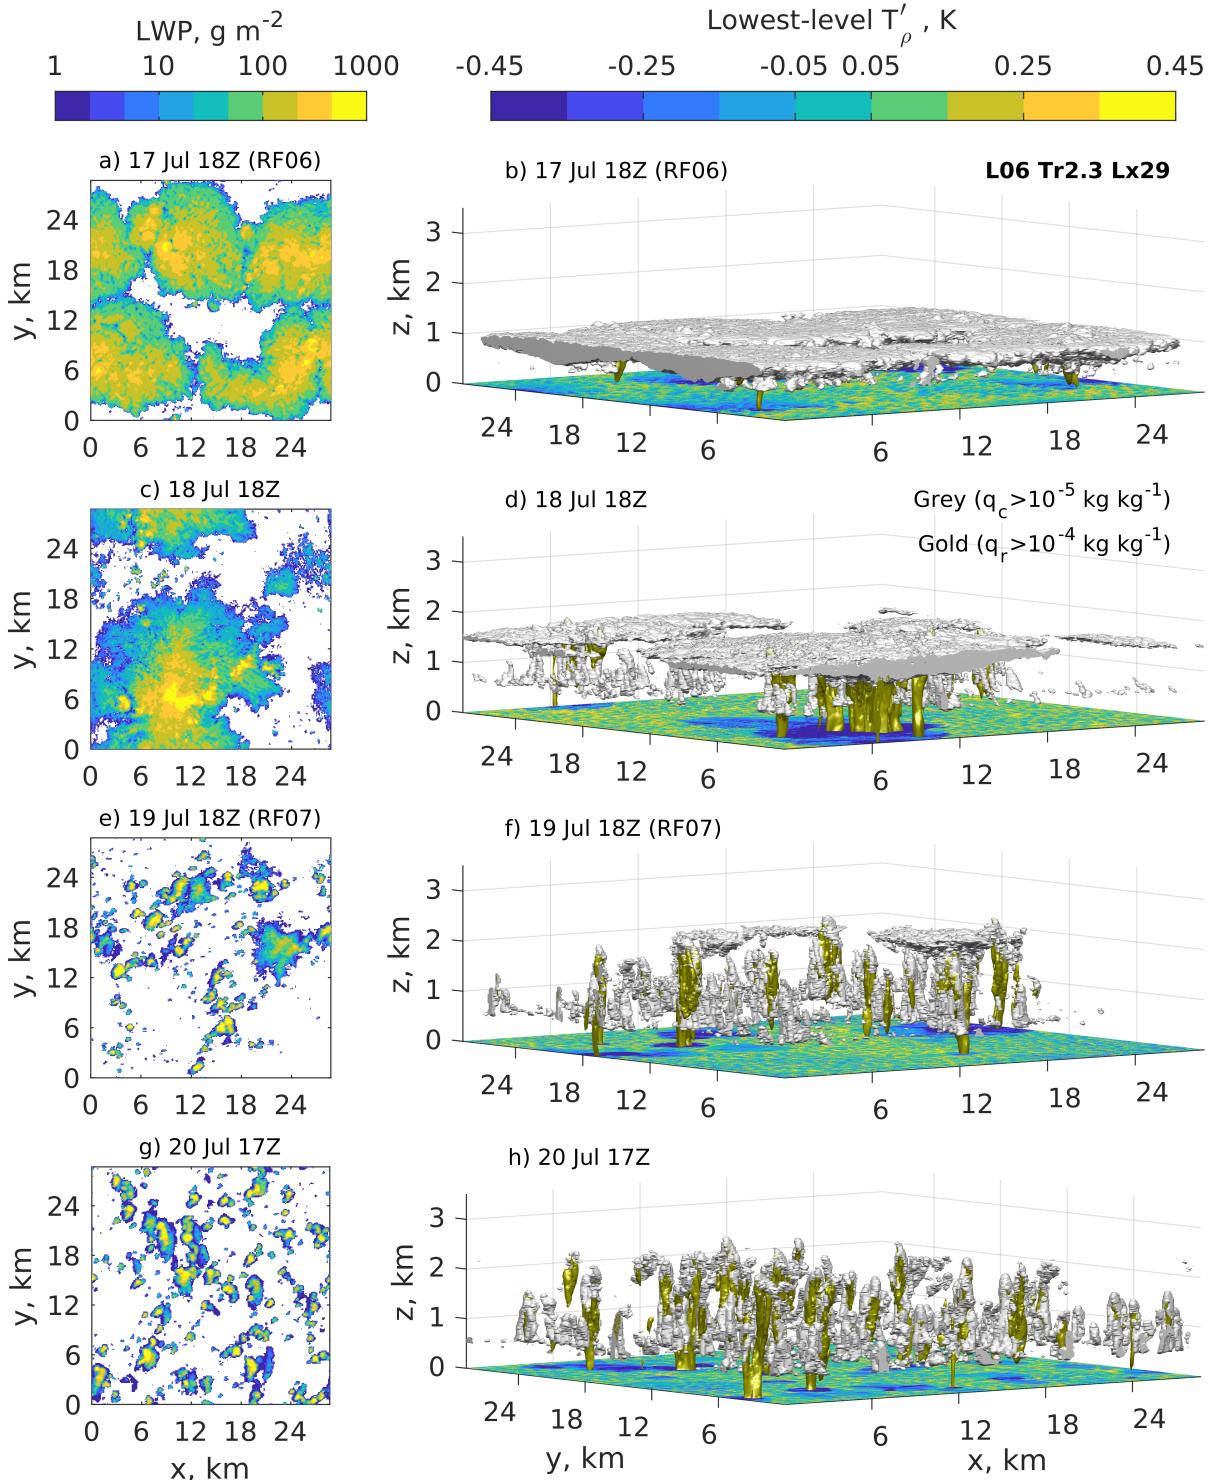

FIG. 7. As in figure 5 but for RF07 Tr2.3 on 19 July 2015.

1065 FIG. 8. (a,c,e,g) Instantaneous liquid water path at four times in simulation Lx29 of case study L06 Tr2.3. No
 1066 color is shown where $\text{LWP} < 0.1 \text{ g m}^{-2}$. (b,d,f,h) Three-dimensional renderings of cloud (grey isosurface depicts
 1067 $q_c > 10^{-5} \text{ kg kg}^{-1}$), precipitation (gold isosurface, $q_r > 10^{-4} \text{ kg kg}^{-1}$) and lowest-grid-level density temperature
 1068 anomaly T'_ρ (color shading on sea surface). The times match those shown in figure 3b-e.

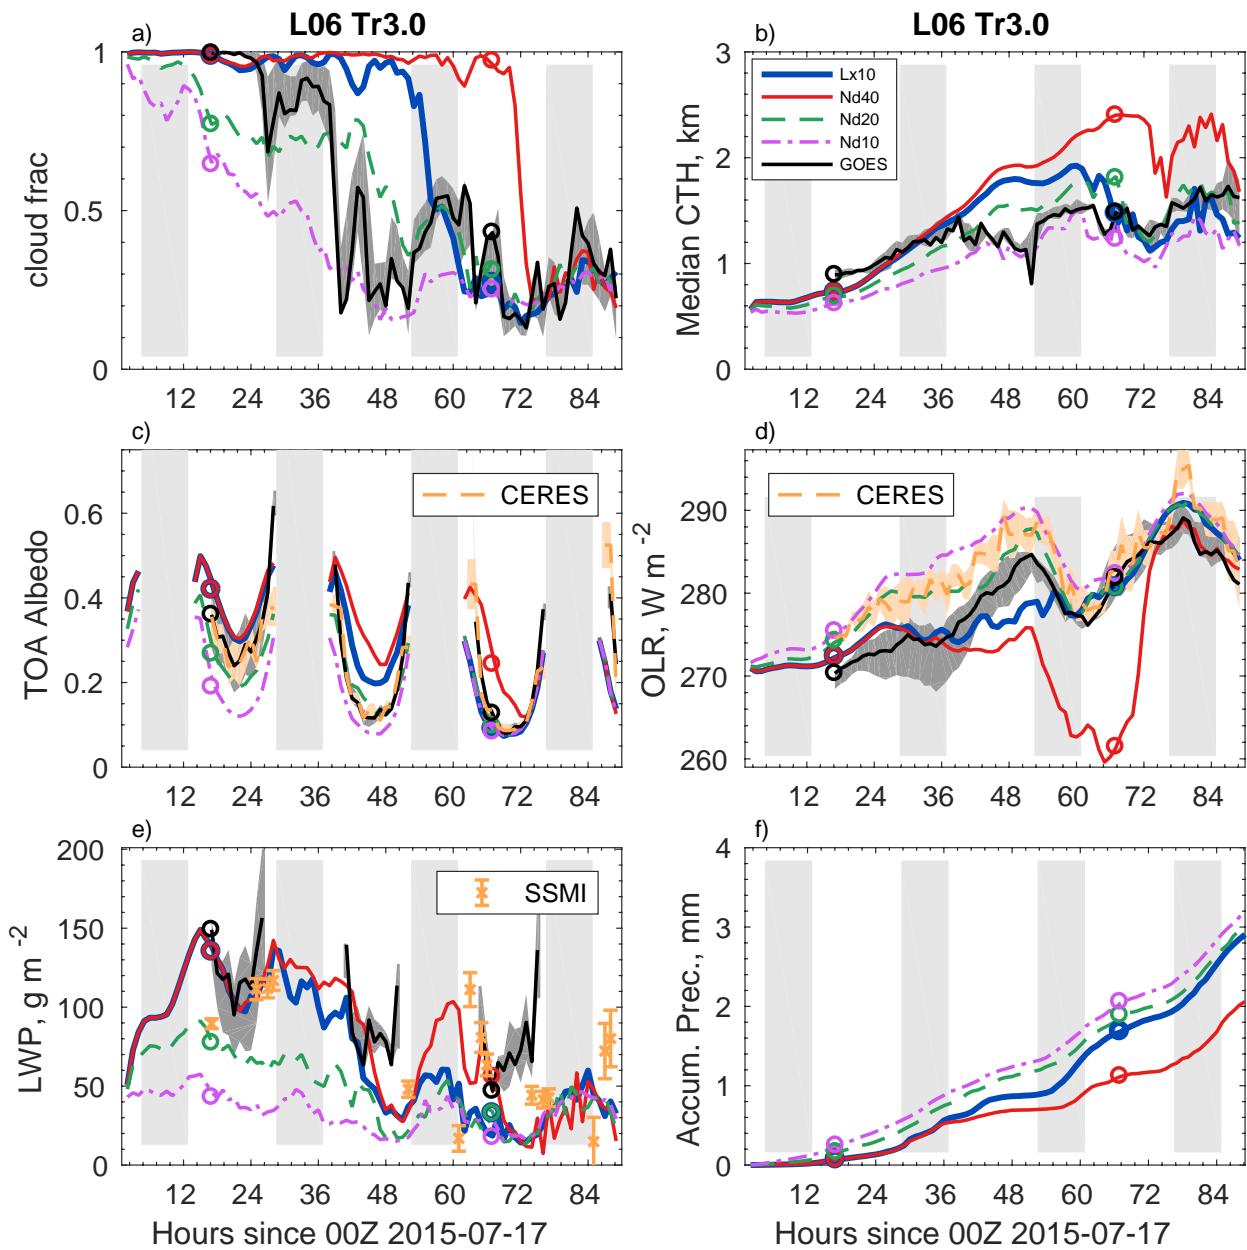

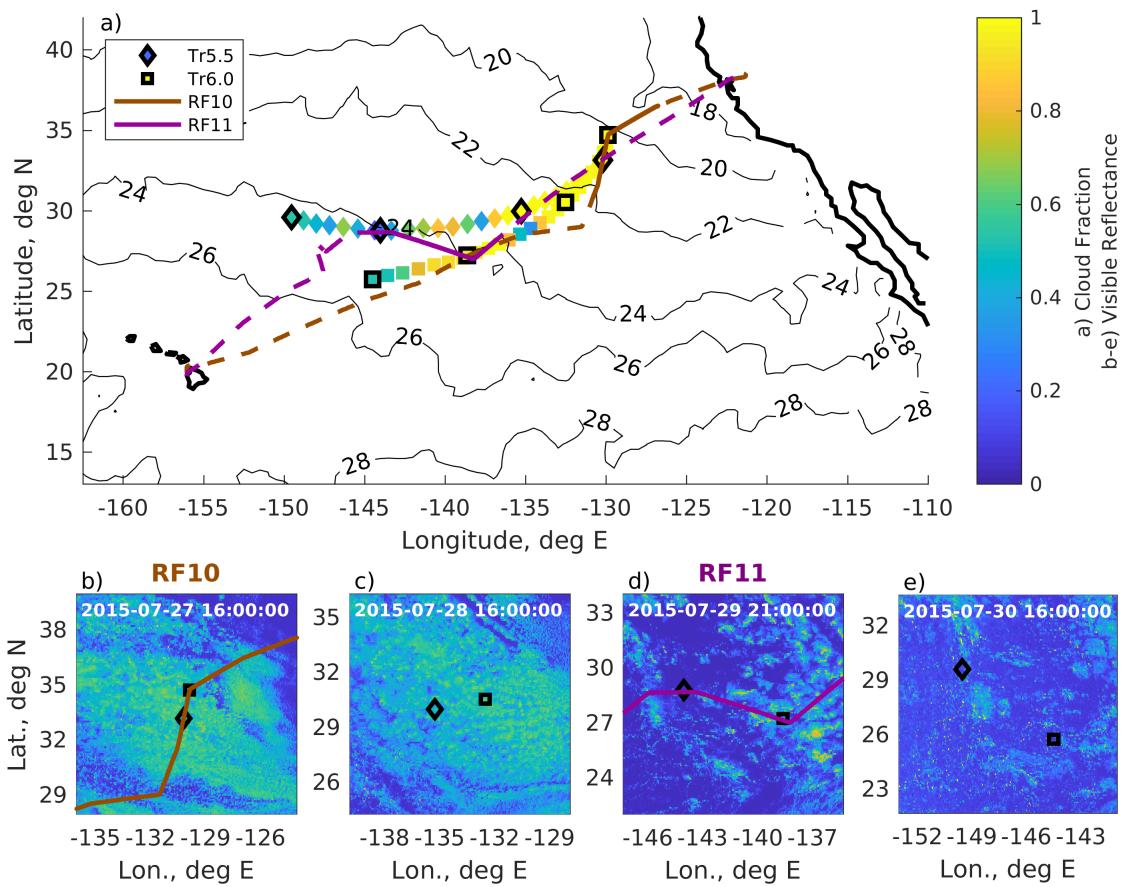

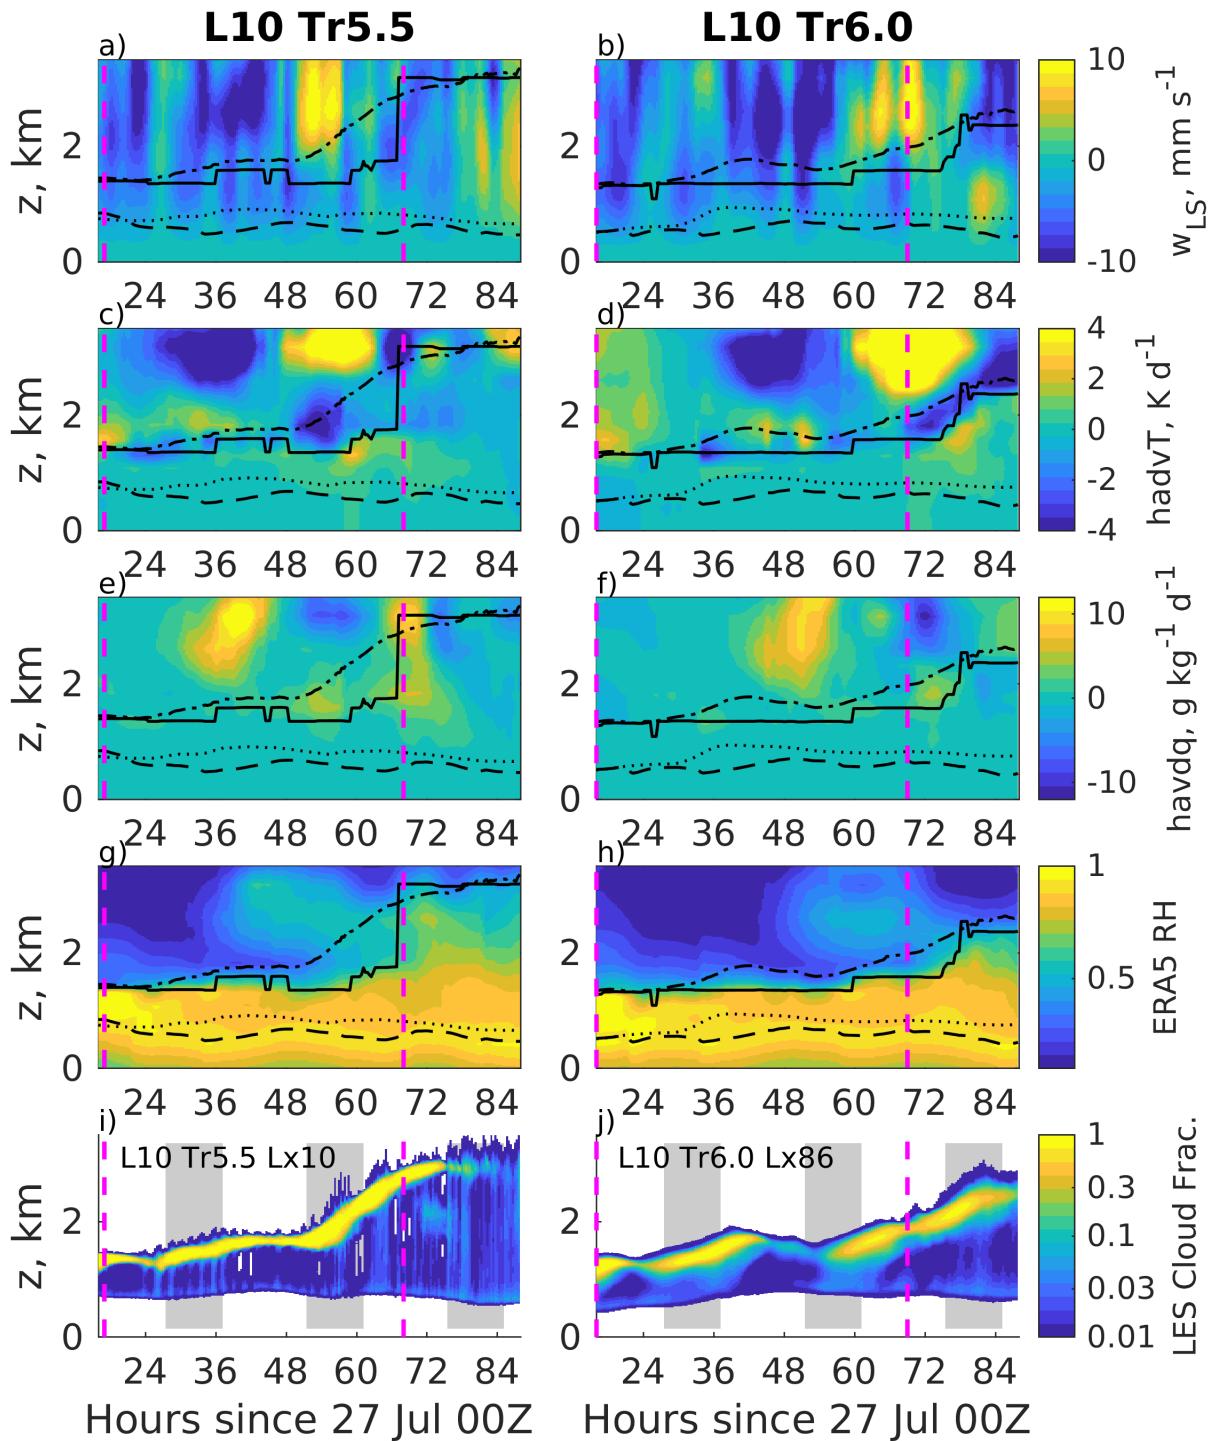

FIG. 9. As in figure 6, except for GOES observations and simulations along trajectory L06 Tr3.0.

1069 FIG. 10. As in figure 3, except showing the L10 Lagrangian case study. The contours show the SST at 12Z on
 1070 27 July.

1071 FIG. 11. As in Figure 4, except for the two L10 trajectories, L10 Tr5.5 and L10 Tr6.0. Time-height profiles of
 1072 cloud fraction are shown for i) L10 Tr5.5 simulation Lx10 and j) L10 Tr6.0 simulation Lx86. The magenta line
 1073 marks the times of the two research flights, RF10 and RF11.

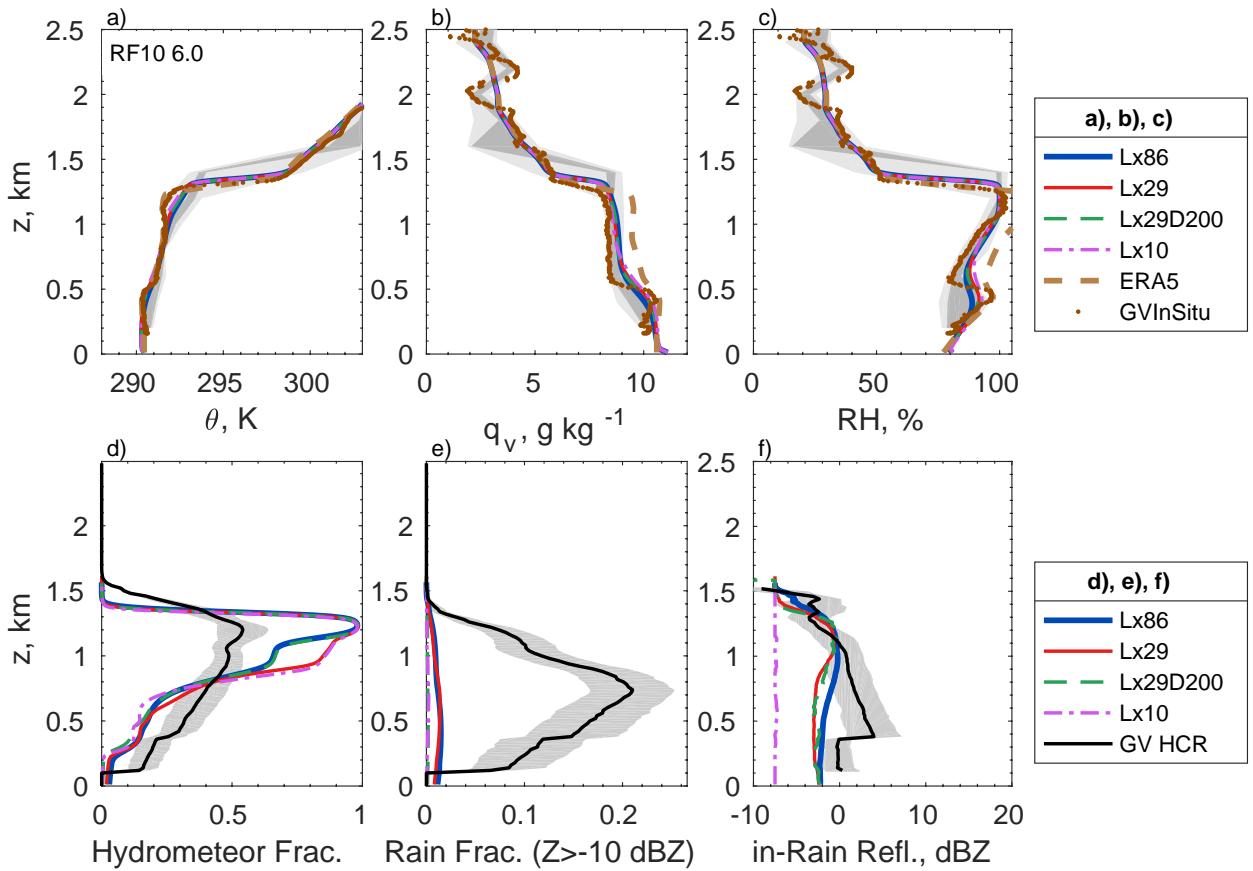

FIG. 12. As in figure 5, but for RF10 Tr6.0 on 27 July 2015

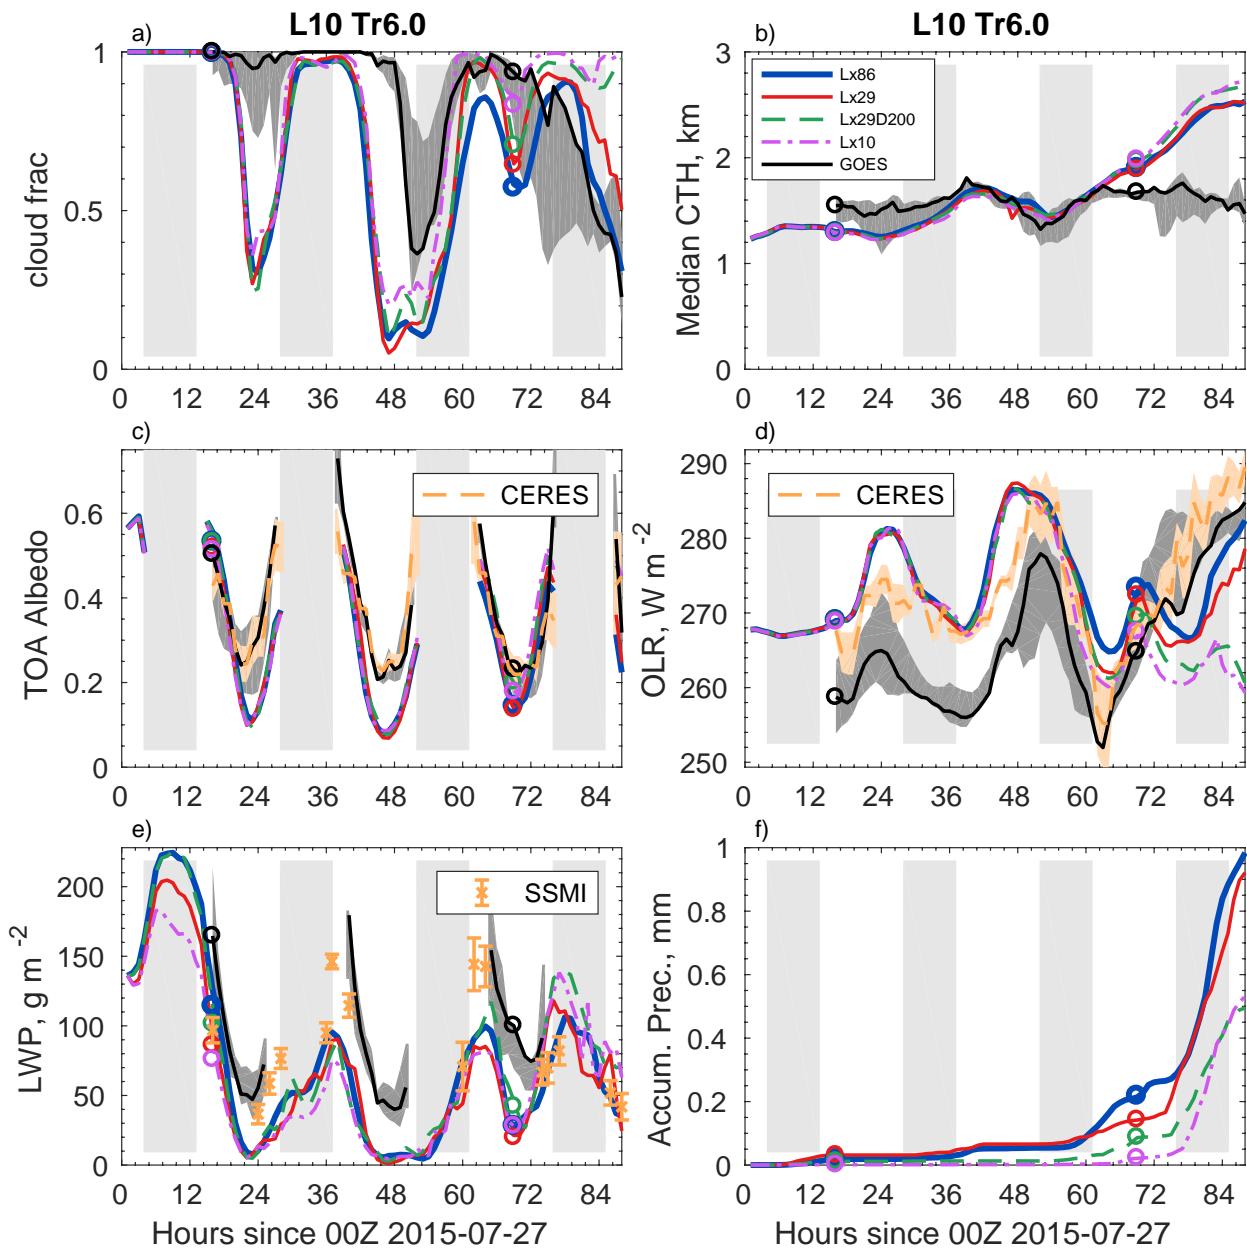

FIG. 13. As in figure 6 but for the L10 Tr6.0 case study.

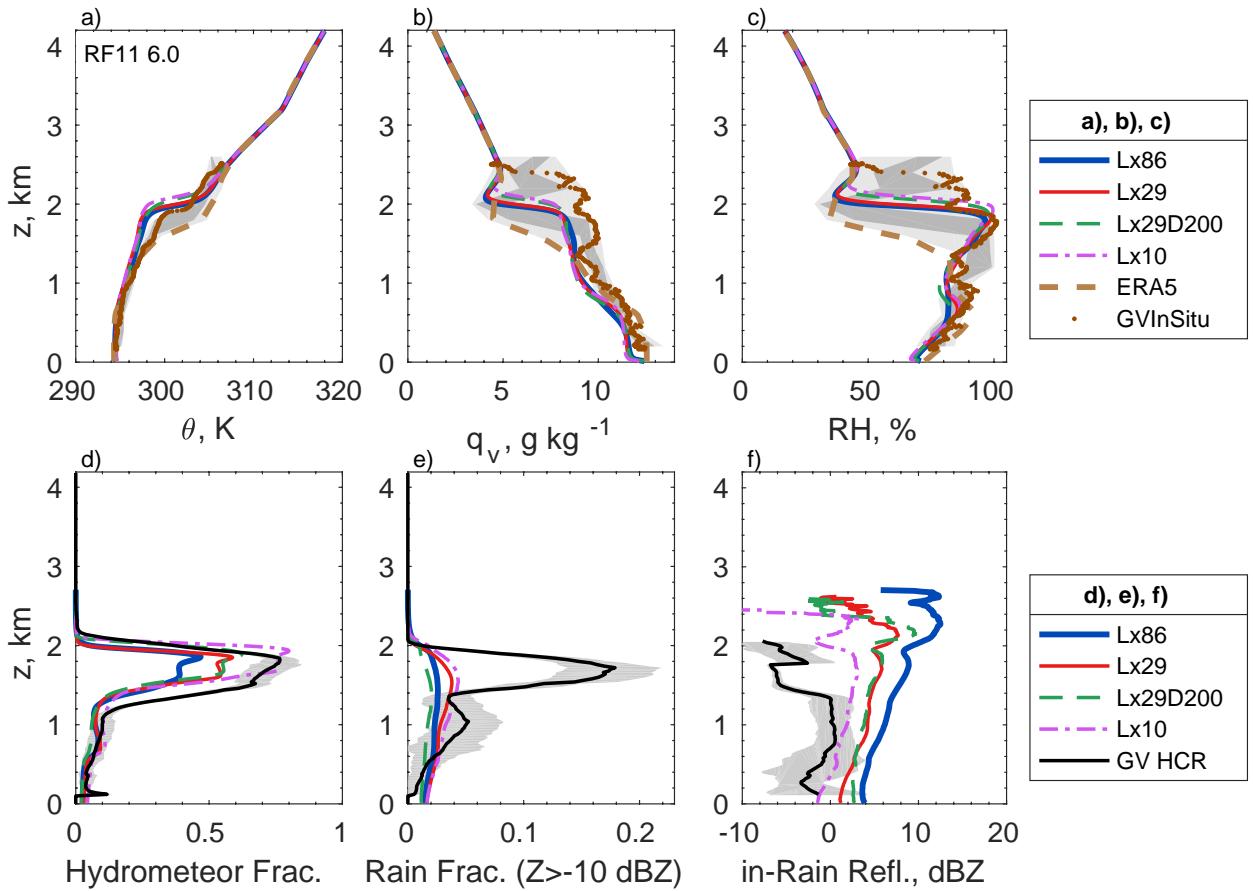

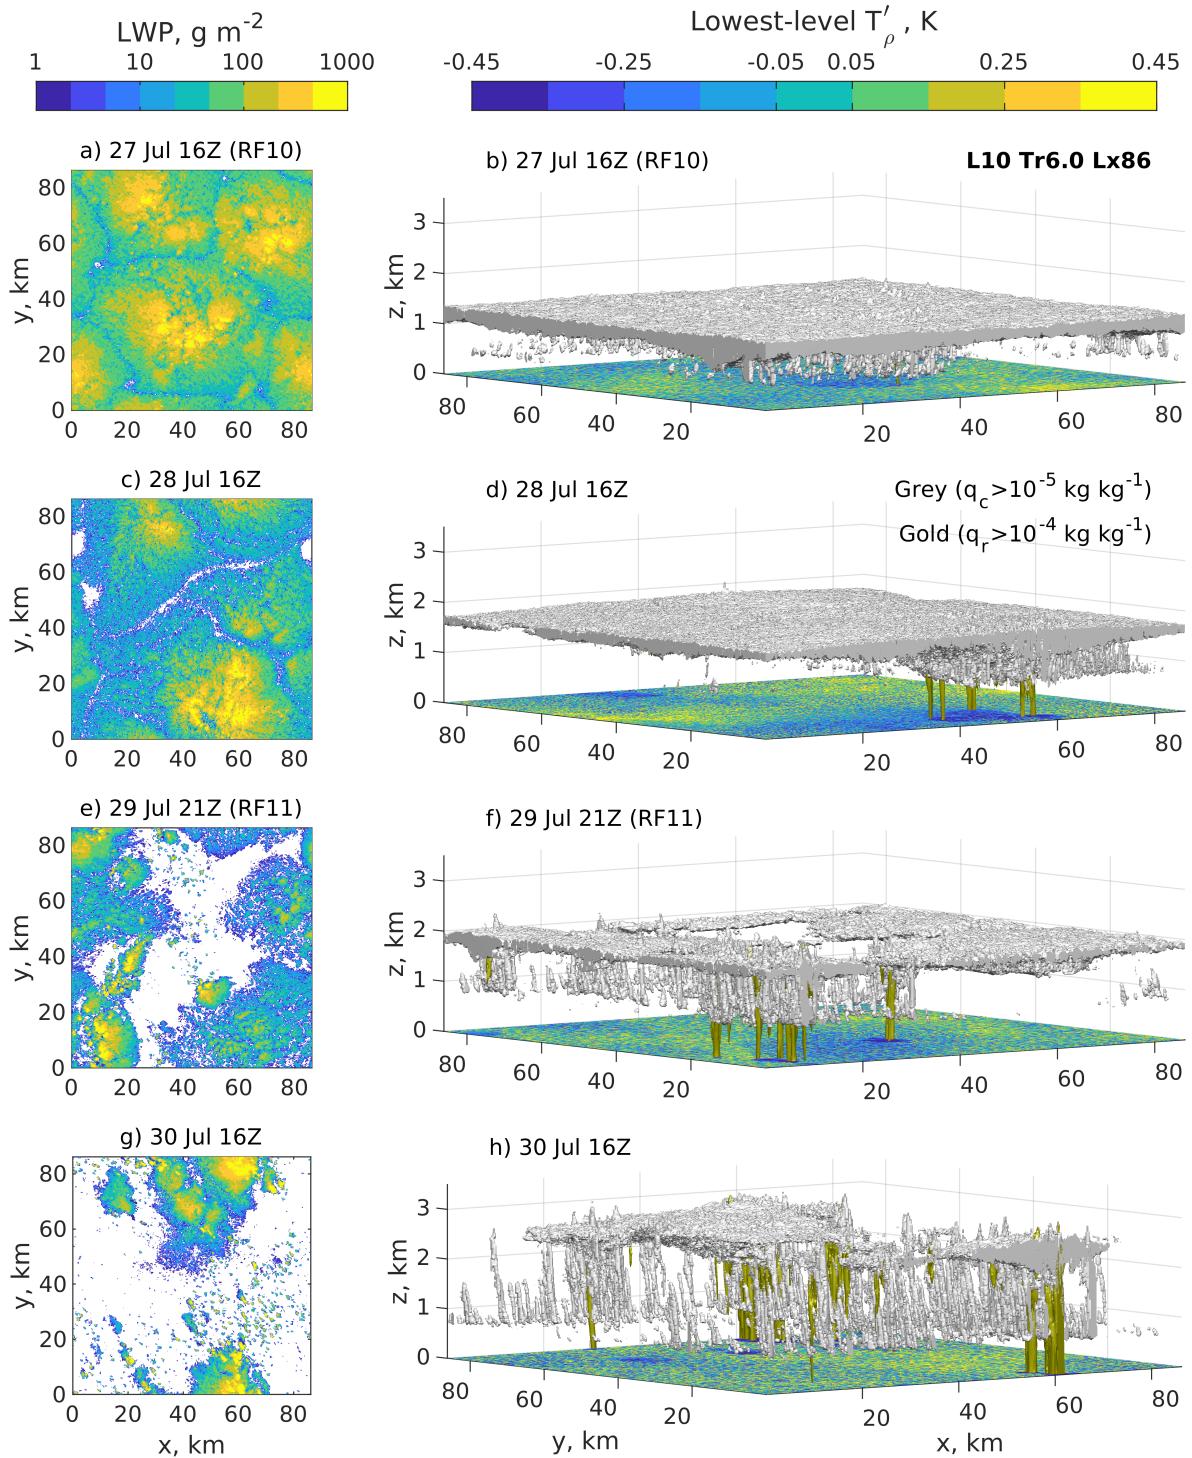

FIG. 14. As in figure 5 but for RF11 Tr6.0 on 29 July 2015.

1074 FIG. 15. As in figure 8, except for the Lx86 simulations of L10 Tr6.0. The times shown correspond to those
 1075 in figure 10b-e.

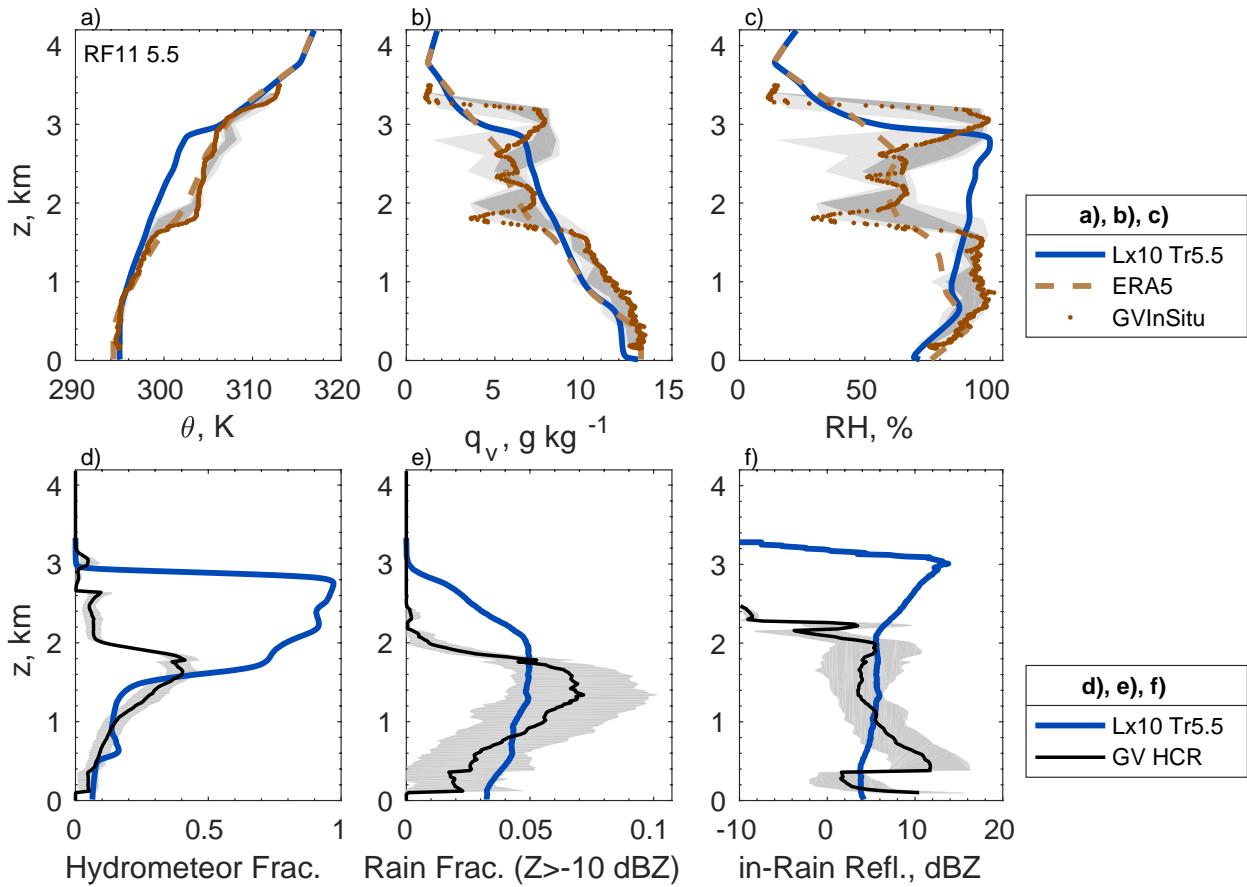

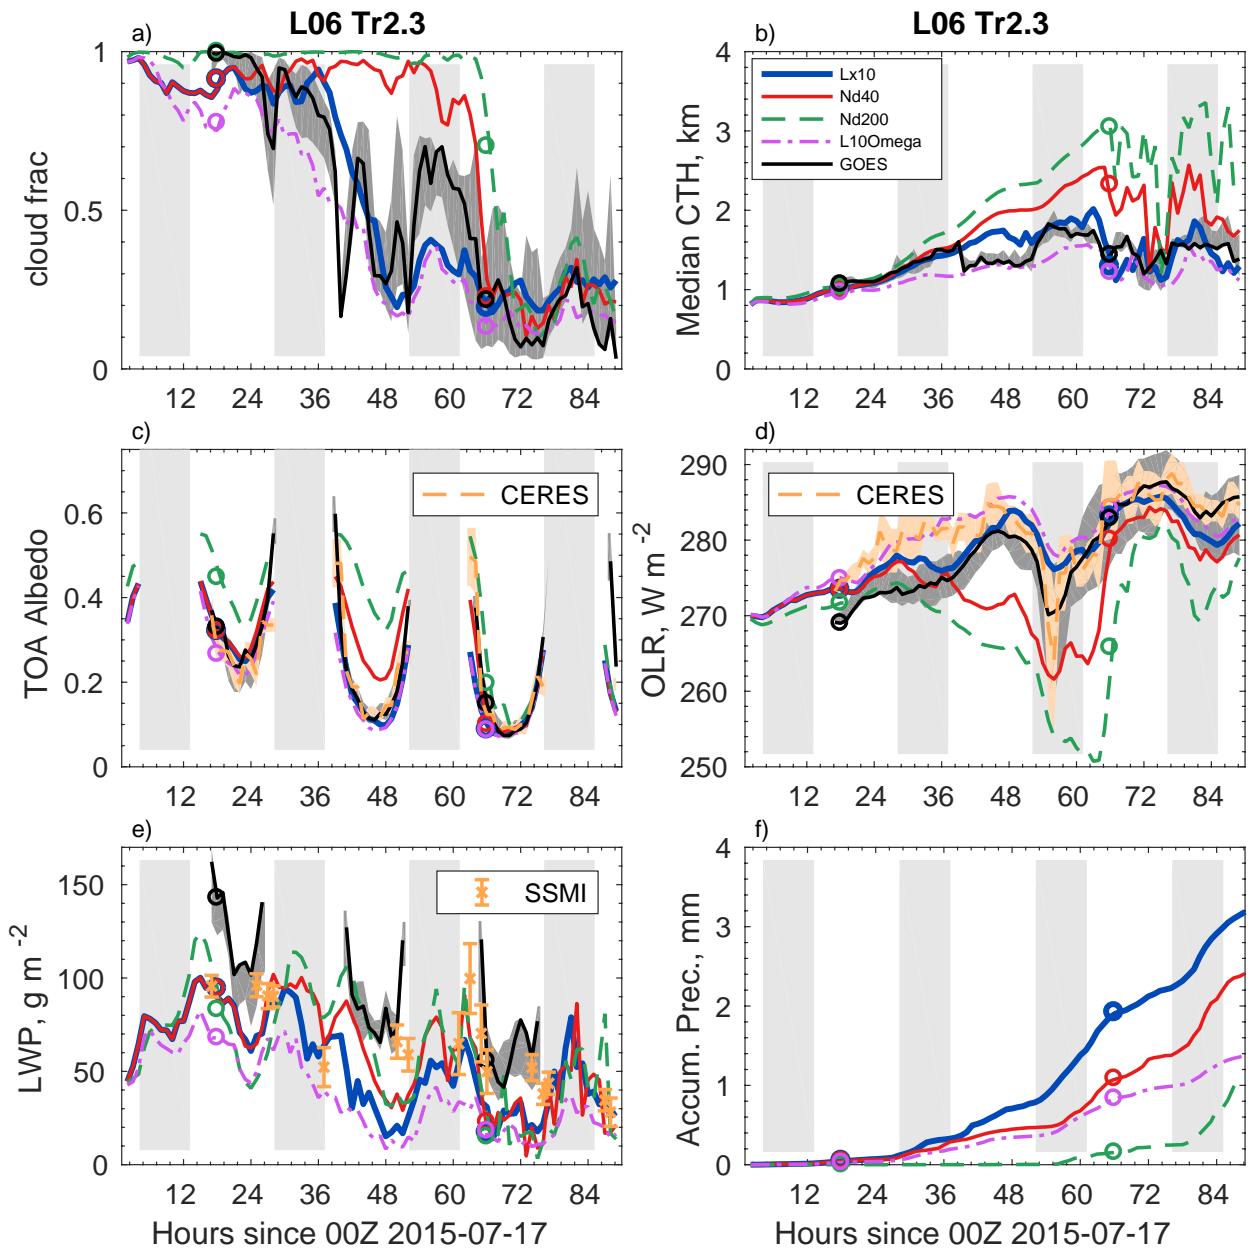

FIG. 16. As in figure 5 but for RF11 Tr5.5 on 29 July 2015.

1076 FIG. 17. As in figure 6, but comparing the additional L06 Tr2.3 sensitivity studies L10Om and Nd200 with
 1077 simulations Lx10 and Nd40.

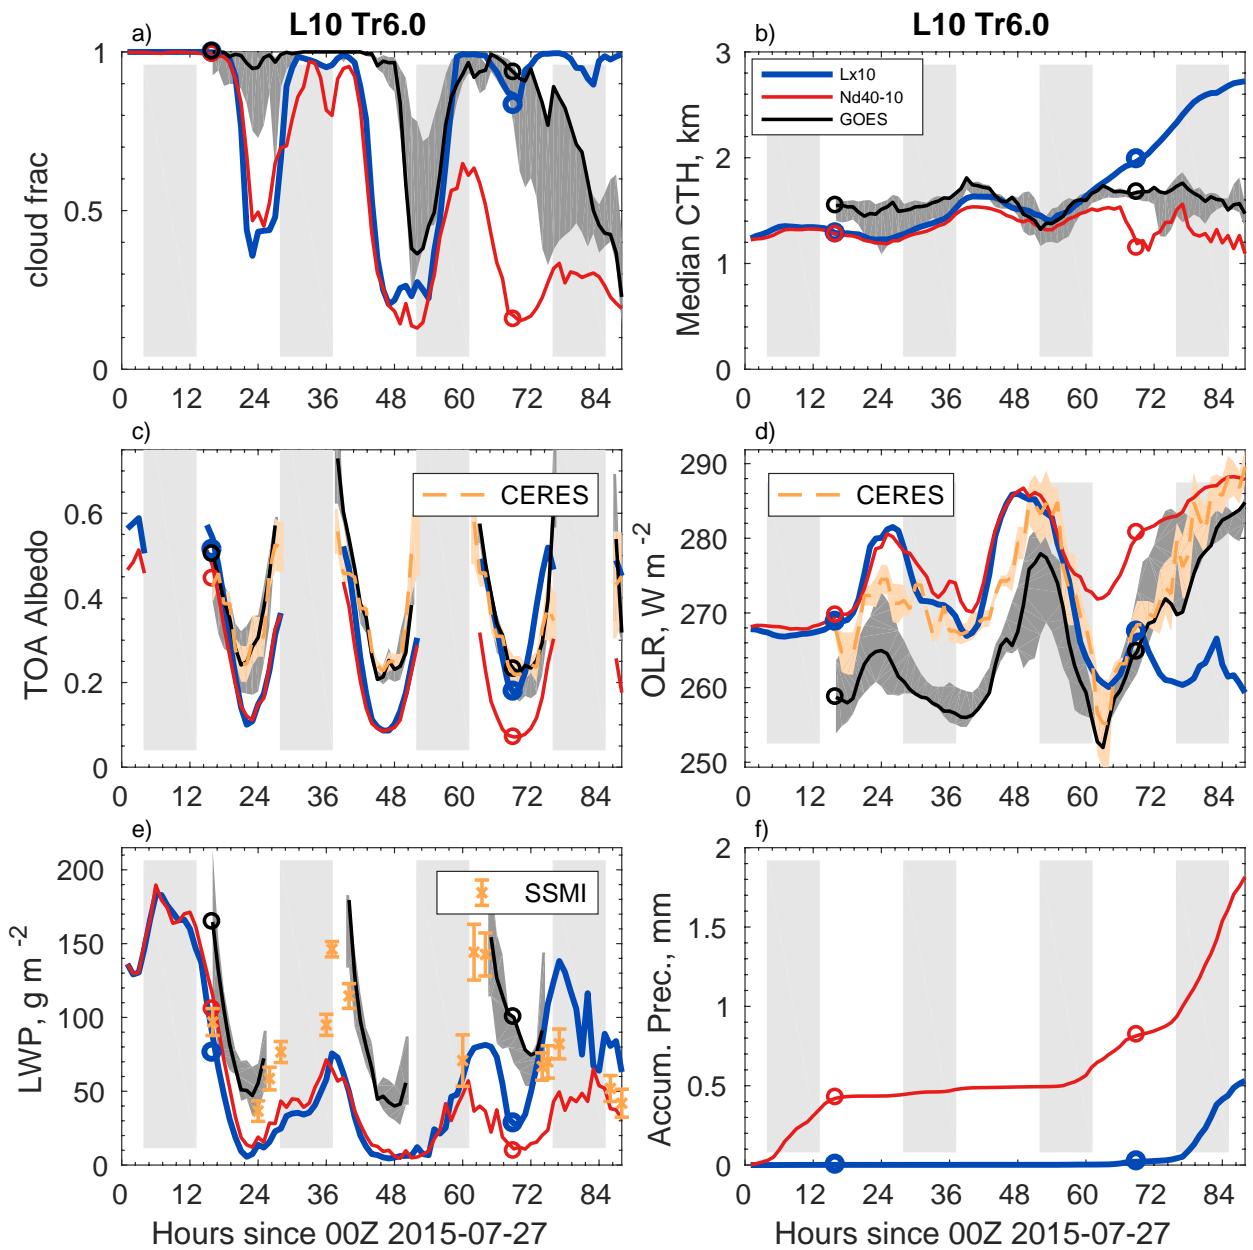

FIG. 18. As in figure 6 but comparing the L10 Tr6.0 sensitivity study L06Nd with simulation Lx10.
