## 14 **Abstract**

15           A sharp contrast in low cloud fraction and boundary layer structure across  
16 the Antarctic sea ice edge during winter is clearly detectable in active satellite  
17 retrievals, which provide an unprecedented view of high latitude clouds during  
18 winter, as well as in reanalysis products and in situ measurements. During polar  
19 winter, sea ice insulates the ocean and prevents heat and moisture transport to the  
20 atmosphere, causing the boundary layer to be convective, moist, warm and cloudy  
21 over open water, and stable, dry, cold and clear over sea ice. The average surface  
22 downward flux of longwave radiation is at least  $39 \text{ W/m}^2$  larger over regions of  
23 open water slightly equatorward of the ice edge than over sea ice slightly poleward  
24 of the ice edge. This enhanced greenhouse effect of the boundary layer over open  
25 water slows heat loss from the ocean and horizontal expansion of sea ice. Several  
26 state-of-the-art global climate models with satellite simulators are compared to  
27 observations. Four out of seven fully coupled models simulate cloudier conditions  
28 equatorward of the sea ice edge than poleward. Other model biases are also  
29 discussed.

## 30 **1. Introduction**

31           Sea ice and marine boundary layer clouds and moisture strongly modulate  
32 high latitude climate. During winter, low clouds and moisture emit longwave (LW)  
33 radiation downward and heat the surface, while sea ice insulates the ocean and  
34 weakens ocean-atmosphere exchanges of heat and moisture. Sea ice formation in

35 the Weddell Sea affects deep water formation and the global circulation of the ocean  
36 [Gordon, 1991]. Since most Antarctic sea ice lasts for less than one year, the growth  
37 of sea ice during winter is an important determinant for how long the ice will persist  
38 into the melt season, and hence the radiative impact it will have. Understanding of  
39 high latitude climate will be improved thorough study of sea ice, low clouds, and  
40 interactions between the two in the observational record, together with evaluation  
41 of models against observations.

42         Satellite active remote sensing provides an unprecedented view of high  
43 latitude clouds during winter. We take advantage of this new technology, as well as  
44 in situ measurements and radiative transfer modeling, to examine low cloud and  
45 boundary layer structure in the vicinity of the Antarctic sea ice edge. We also  
46 provide a novel test for climate models based on their ability to capture the contrast  
47 in low cloud on either side of the sea ice edge.

48         Interactions between sea ice and the atmospheric boundary layer have  
49 previously been studied, but focus on this topic has generally been on Arctic sea ice.  
50 Two exceptions are [Bromwich et al., 2012] who first pointed out that the total  
51 cloud fraction observed from active satellite retrievals is ~10-20% lower in sea ice  
52 covered regions of the Southern Ocean than over open water to the north, and  
53 [Fitzpatrick and Warren, 2007] who used ship-based measurements of downwelling  
54 shortwave (SW) radiation over the Southern Ocean to show that clouds tend to be  
55 optically thicker over open water than over sea ice in austral spring and summer. In  
56 the Arctic summer and early fall, low clouds have been observed to be more  
57 abundant and optically thicker over open water than over sea ice from active

58 satellite remote sensing products [Kay and Gettelman, 2009; Palm et al., 2010] and  
59 from surface observers [Eastman and Warren, 2010]. On the other hand, [Schweiger  
60 et al., 2008] found that regions of low sea ice cover coincide with enhanced mid-  
61 level cloudiness and reduced low cloud cover in the Arctic during autumn using  
62 passive satellite retrievals. It has also been argued that boundary layer moisture (or  
63 lack thereof) triggers the onset of sea ice melt and freeze-up when advected over  
64 Arctic sea ice [Kapsch et al., 2013] and that a warmer, moister boundary layer has  
65 amplified Arctic sea ice decline in recent years [Serreze et al., 2009; Screen and  
66 Simmonds, 2010; Boisvert and Stroeve, 2015].

67 Most of the studies mentioned above were performed on the Arctic, while the  
68 Southern Ocean has received relatively little attention. In this study we provide, for  
69 the first time, a comprehensive analysis of low cloud and boundary layer structure  
70 near the Antarctic sea ice edge during winter.

## 71 **2. Data and Methods**

72 Cloud observations are taken from the Cloud-Aerosol Lidar with Orthogonal  
73 Polarization (CALIOP) instrument onboard the Cloud-Aerosol Lidar and Infrared  
74 Pathfinder Satellite Observation (CALIPSO). CALIOP is an atmospheric lidar that  
75 measures high vertical resolution profiles of clouds [Winker et al., 2007]. Because  
76 CALIOP is an active instrument, retrievals are not affected by low sunlight or near-  
77 surface inversions, two conditions that make retrievals of low clouds over sea ice  
78 highly uncertain or impossible with passive remote sensing techniques. As an  
79 example of the challenge of cloud detection over high latitudes with passive

80 instruments, [Liu et al., 2004] found that during polar night over 40% of all clouds  
81 went undetected by the cloud mask algorithm of the Moderate-resolution Imaging  
82 Spectroradiometer (MODIS) used at that time. The algorithm has since been  
83 improved, but detection of low clouds over ice covered polar regions remains a  
84 major challenge for passive instruments [Ackerman et al., 2008]. On the other hand,  
85 the signal-to-noise ratio of CALIOP is maximized in the absence of sunlight, making  
86 it well suited for studying clouds during polar night.

87         We use the Global Climate Model-Oriented CALIPSO Cloud Product (GOCCP)  
88 [Chepfer et al., 2010; CALIPSO, 2015], which provides monthly-mean cloud  
89 incidence on a  $2^\circ \times 2^\circ \times 0.48$  km (longitude, latitude, height) grid. For a given grid box  
90 and month, cloud incidence is defined as the number of times a cloud was positively  
91 identified divided by the total number of scenes in which the lidar was not fully  
92 attenuated above the grid box. The vertical (horizontal) resolution of CALIOP is 30  
93 m (330 m) below 8 km and 60 m (1000 m) above, with a total of 583 vertical levels.  
94 Interpolating to the relatively coarse GOCCP vertical grid (40 levels) significantly  
95 increases the signal-to-noise ratio and provides a grid that is ideal for comparison  
96 with GCMs [Chepfer et al., 2010].

97         We also use observations of passive microwave sea ice concentration (SIC)  
98 from the National Snow and Ice Data Center [Peng et al., 2013; NOAA/NSIDC, 2015]  
99 and cloud liquid water path from the Multi-Sensor Advanced Climatology of Liquid  
100 Water Path dataset [Elsaesser et al., 2015]. Temperature and specific humidity fields  
101 from European Center for Medium-Range Weather Forecasts Reanalysis (ERA  
102 Interim; [Dee et al., 2011; ECMWF, 2015]) are used. All satellite and reanalysis data

103 analyzed are monthly-mean fields during the time period from June, 2006 to August,  
104 2014.

105         Additionally, we use in situ measurements of air temperature, wind and  
106 surface energy budget terms over the Weddell Sea during winter. Temperature and  
107 wind data are taken from soundings obtained on a cruise that traversed the Weddell  
108 Sea during June-August 2013 [König-Langlo et al., 2006; König-Langlo, 2013] and  
109 surface energy budget measurements were obtained on a drifting ice floe in the  
110 western Weddell Sea during April-May 1992 as part of the Ice Station Weddell  
111 campaign [Gordon et al., 1993; Ice Station Weddell, 1993]. The soundings were  
112 taken once daily, released from a height of 10 m, and have ~30 m vertical  
113 resolution in the lower troposphere. Sounding data were linearly interpolated to a  
114 vertical grid with a spacing of 30 m. A total of 50 soundings were taken poleward of  
115 60°S, and of these soundings, half were taken between 60-65°S and half were taken  
116 poleward of 65°S. Hourly-averages of the surface heat budget measurements are  
117 analyzed. The latent and sensible heat terms were computed from eddy correlation  
118 measurements.

119         Finally, we use output from seven GCMs that participated in the Coupled  
120 Model Intercomparison Project Phase 5 (CMIP5) [Taylor et al., 2012], including  
121 output from the CALIPSO simulator [Chepfer et al., 2008]. Models in fully coupled  
122 and atmosphere only configurations are evaluated, and the first ensemble member  
123 for each model is used.

124

## 125 **3. Observed winter low cloud and boundary layer structure over** 126 **the Southern Ocean**

### 127 **3.1 Satellite Observations**

128 Figure 1 shows 2006-2014 winter climatology of cloud incidence between  
129 0.96-1.44 km along with the 35% SIC contour. Throughout this study the latitude of  
130 the sea ice edge is defined as the northernmost point at which the SIC is 35% at each  
131 longitude. A clear and sharp contrast in cloudiness at the 0.96-1.44 km level occurs  
132 between latitudes on either side of the ice edge, with cloud incidence generally  
133 ~30% over open water and ~10% over ice. The gradient of cloud incidence across  
134 the ice edge is weakest in the Western Pacific and Southern Indian Ocean (20°E –  
135 160°E) where the ice edge is closest to shore. Further analysis is carried out over  
136 the Weddell and Ross Seas (defined as 50°W-0°E and 130°W-170°E, respectively;  
137 Figure 2) where the ice edge is farthest offshore.

138 We now consider the vertical profile of cloudiness, temperature and  
139 humidity in the lower troposphere. For each gridpoint and time (only monthly-  
140 means from June, July and August (JJA) between 2006-2014 are considered), the  
141 meridional distance between the gridpoint and the ice edge was computed. Data  
142 were then composited by meridional distance from the ice edge in bins of width 0.5°  
143 latitude, and the mean of each bin computed. This procedure was also done on the  
144 JJA-mean of each year, and the main conclusions are the same using either monthly  
145 or seasonal averages.

146 Figure 2b and 2f show the vertical profiles of mean cloud incidence in the  
147 lower troposphere as a function of meridional distance from the sea ice edge in the  
148 Weddell and Ross Seas, respectively. The boundary layer is, on average, deeper and  
149 cloudier equatorward of the sea ice edge than poleward. The mean total low cloud  
150 fraction (LCF), defined as cloud fraction below the 680 hPa level ( $\sim 3.2$  km), as well  
151 as the mean SIC are shown in Figure 3c and 3g (see Appendix). The mean SIC can be  
152 split into three regions: an “ice” zone in which  $SIC \sim 100\%$  that occurs poleward of  $2^\circ$   
153 south of the ice edge, an “open water” zone in which  $SIC \sim 0\%$  that occurs  
154 equatorward of  $1^\circ$  north of the ice edge, and a “transition” region between. The  
155 mean LCF in the “ice” zone is 50% to 55% and bins within the “ice” zone have a  
156 nearly uniform LCF to within the 95% measurement uncertainty. This is also true  
157 for the “open water” zone, where mean LCF is 65% to 70%. The mean LCF is  
158 significantly larger in the “open water” zone than the “ice” zone (i.e. there is no  
159 overlap between the 95% confidence interval of any bin in the “open water” zone  
160 with any bin in “ice” zone). Across the “transition” zone, LCF increases smoothly as  
161 SIC decreases.

162 Finally, vertical profiles of mean potential temperature and specific humidity  
163 from reanalysis as a function of meridional distance from the ice edge are shown in  
164 Figure 3d and 3h. The boundary layer is clearly more stable over sea ice than over  
165 open water, as can be seen by the vertical spacing in the potential temperature  
166 contours. Near the surface, temperatures are close to the freezing temperature over  
167 open water and drop more rapidly poleward of the ice edge. Boundary layer specific

168 humidity values are also nearly a factor of two larger over open water than over sea  
169 ice.

## 170 **3.2 Ground-based Observations**

### 171 **a. Boundary layer vertical structure from soundings**

172 Soundings can resolve the vertical structure of the boundary layer and  
173 provide further insight into the physical process at work. We analyze soundings  
174 taken from a cruise that traversed the Weddell Sea during June-August 2013 [König-  
175 Langlo, 2013]. The cruise track is shown in Figure 3.

176 We begin with a brief description of sea ice in the Weddell Sea during  
177 midwinter as observed from cruises. The sea ice edge is typically found between 60-  
178 65°S and advances northward by several degrees latitude over the course of the  
179 winter (Figure 1). Near the outer edge of the sea ice there is a ~250 km north-south  
180 band of fragmented pancake ice with pockets of exposed seawater. Farther south,  
181 sea ice is organized into vast floes that cover the ocean surface nearly completely  
182 [Wadhams et al., 1987, their Figure 12]. Sounding data is composited into  
183 measurements made between 60-65°S and poleward of 65°S. It is likely that many of  
184 the soundings obtained between 60-65°S were taken above or close to regions of  
185 open water, either within the band of fragmented pancake ice or north of the ice  
186 edge, and the soundings poleward of 65°S were taken over consolidated pack ice.

187 Figure 4 shows the probability density function of temperature at each  
188 height recorded by the soundings between 10-1500 m. This was computed by  
189 binning the data at each level into bins of width 2°C, computing the frequency of

190 occurrence of each bin, and normalizing by the number of soundings. Clear  
191 bimodality in the soundings between 60-65°S is seen, which illustrates the influence  
192 of sea ice on the boundary layer structure. The warm mode closely follows a moist  
193 adiabat with a surface temperature of -1.8°C, the approximate freezing temperature  
194 of seawater in the Southern Ocean. This warm mode forms where the atmosphere is  
195 in contact with open water, and under such circumstances the boundary layer is  
196 convective and moist. Only the cold mode is found poleward of 65°S because the  
197 presence of sea ice diminishes the heat and moisture fluxes to the atmosphere. Low-  
198 level inversions are common in the cold mode (e.g. Figure 5).

199         Low-level jets are also frequently seen in the soundings, indicating the  
200 presence of a stable boundary layer (Figure 5). A low-level jet is defined as a local  
201 maximum in wind speed of at least 2 m/s that is below 1 km. Low-level jets exist  
202 above stable boundary layers and, at least in temperate latitudes, are initiated when  
203 the boundary layer transitions from convective to stable. The sudden shoaling of the  
204 boundary layer during this transition causes a reduction in drag from turbulent  
205 momentum flux, and therefore a sudden increase in wind speed, at heights above  
206 the stable boundary layer but below the former convective boundary layer top. At  
207 these heights the wind undergoes inertial oscillations that are nearly undamped  
208 because of the stable boundary layer below, and wind speeds can therefore exceed  
209 geostrophic values [Blackadar 1957; Thorpe and Guymer, 1977].

210         Low-level jets were identified in 31 of the 50 soundings taken poleward of  
211 60°S. The low-level jets tend to be oriented toward the north west and west, and  
212 within the jet core, wind speeds in excess of 15 m/s are not uncommon (Figure 5).

213 The mechanism that initiates low-level jets over Antarctic sea ice during winter is  
214 not fully understood. Low-level jets were identified at locations throughout the  
215 cruise, but were especially prevalent near the Antarctic Peninsula (not shown),  
216 suggesting that some of the observed jets are driven by outflow from the barrier  
217 winds in the western Weddell Sea. The barrier winds are strong, low-level winds  
218 that parallel the mountain range on the Antarctic Peninsula, and are driven by a  
219 pressure gradient that develops when low-level easterly flow across the southern  
220 Weddell Sea is obstructed by the mountains on the Antarctic Peninsula  
221 [Schwerdtfeger, 1973; Parish, 1983]. It has been hypothesized that, away from the  
222 influence of the barrier winds, low-level jets over sea ice are initiated by advection  
223 of air from the convective boundary layer that forms above open water. This warm  
224 advection may temporarily deepen the boundary layer and erode the low-level jet.  
225 Then the air mass cools, a stable boundary layer forms, and a new low-level jet is  
226 initiated [Andreas et al., 2000]. Katabatic winds may also drive low-level jets near  
227 the Antarctic coast.

#### 228 **b. Surface energy budget over sea ice in the Weddell Sea**

229 The surface energy budget must be examined in order to understand the  
230 extent to which the boundary layer influences the development of Antarctic sea ice.  
231 We analyze surface energy budget measurements taken on a drifting ice floe called  
232 the Ice Station Weddell during April-May 1992 [Gordon et al., 1993]. The drift path  
233 is shown in Figure 3. It is important to bear in mind that the Ice Station Weddell  
234 measurements were made in the interior of the Weddell Sea over a thick slab of

235 multi-year ice for only two months in early winter, and therefore may not be  
236 representative of the Southern Ocean as a whole.

237         The surface heat budget measurements are shown in Figure 6, and are  
238 dominated by the LW fluxes. The net flux is typically negative, indicating heat loss  
239 from the ice. To leading order, the heat loss is balanced by upward conduction of  
240 heat that is released at the ice-ocean interface as seawater freezes, and by heat  
241 supplied from the ocean [Thorndike, 1992]. Comparison of the LW fluxes reveals  
242 that heat loss from the ice is an order of magnitude larger when the downward LW  
243 flux is relatively small (i.e. when the boundary layer is clear, cold and dry) than  
244 when the downward LW flux is large (i.e. when the boundary layer is warm, cloudy  
245 and moist). This can be seen by comparing the red and black lines in Figure 6b. The  
246 red line shows the mean surface downward LW flux as a function of upward LW  
247 flux, which was computed by binning the data by downward LW flux into bins of  
248 width  $10 \text{ Wm}^{-2}$  and then computing the mean upward LW flux and 95% confidence  
249 interval for each bin. The confidence interval has been adjusted to account for serial  
250 correlation of the data [Bretherton et al., 1999; their equation 31]. In the Arctic  
251 winter, the net surface LW flux over sea ice also has bimodal behavior, with a  
252 preferred value of  $\sim -40 \text{ W/m}^2$  under clear skies or thin ice clouds and  $\sim 0 \text{ W/m}^2$   
253 during cloudy conditions [Stramler et al., 2010].

254         The net surface heat flux is an important determinant of the rate of sea ice  
255 thickening during winter. On seasonal timescales, there is approximate heat balance  
256 | in the sea ice between heat flux to the atmosphere ( $F_{atm}$ ) and ocean ( $F_{ocn}$ ) and  
257 | latent heating from the formation of new ice:

258

$$-L \frac{dh}{dt} \approx F_{atm} + F_{ocn}$$

259

260 where  $L = 3 \times 10^8$  J/m<sup>3</sup> is the latent heat of fusion of sea ice,  $h$  is the sea ice  
261 thickness, and  $F_{atm}$  and  $F_{ocn}$  are defined to be positive when heat flows into the ice.  
262 We neglect heat storage within the ice because, on seasonal timescales, it is much  
263 smaller than latent heating from the formation of new ice [Thorndike, 1992].  
264 Horizontal heat transport is also neglected.

265 The observed net surface heat loss to the atmosphere has a mean value of  
266  $F_{atm} = -19.0 \pm 0.5$  Wm<sup>-2</sup> for clear and dry conditions (defined as scenes in which  
267 the downward LW flux is less than 200 Wm<sup>-2</sup>) and  $F_{atm} \approx -8.0 \pm 0.5$  Wm<sup>-2</sup> for  
268 cloudy and humid conditions (defined as scenes in which the downward LW flux is  
269 greater than 200 Wm<sup>-2</sup>). Using the heat balance described above, this implies that  
270 the mean ice growth rate is approximately 3 mm/day larger for clear and dry  
271 conditions than for cloudy and humid conditions, assuming the same ocean heat  
272 flux. Since Antarctic sea ice typically reaches a thickness of  $\sim 0.5$  m by the end of  
273 growth season [Kurtz and Markus, 2012], these observations suggest that  
274 temperature and moisture advection over sea ice can substantially reduce ice  
275 thickness on seasonal timescales.

#### 276 **4. Computing surface downward LW flux near the sea ice edge**

277           The surface energy budget measurements taken from Ice Station Weddell  
278 provide valuable insight into the energetics of Antarctic sea ice growth, but are very  
279 limited in both space and time. It remains to be seen whether or not there is a jump  
280 in surface downward LW flux across the sea ice margin due to differences in  
281 boundary layer properties on either side of the ice edge, and if so, if the difference in  
282 LW flux is large enough to influence the horizontal expansion of sea ice during  
283 winter. We examine this question using the one-dimensional Rapid and Accurate  
284 Radiative Transfer Model for GCMs [Mlawer et al., 1997; Clough et al., 2005; Iacono  
285 et al., 2008] forced with atmospheric temperature and humidity profiles from  
286 reanalysis and cloud liquid water path (LWP) from satellite observations over the  
287 Weddell Sea during JJA.

288           In order to examine the winter surface energy budget on either side of the  
289 sea ice edge we again sort data into an “open water” and “sea ice” composite,  
290 defined as all scenes 1°-3° equatorward and 2°-4° poleward of the ice edge,  
291 respectively. Sea ice cover in the “open water” (“sea ice”) region is approximately  
292 zero (complete) (Figure 2c). The temperature and humidity profiles for the “open  
293 water” and “sea ice” composites are shown in Figure 7. The profiles are  
294 characterized by a relatively cold, stable and dry boundary layer over sea ice and a  
295 warm and moist boundary layer over open water, which is qualitatively in  
296 agreement with the soundings presented earlier. The model was run with all  
297 profiles of temperature and humidity during the period of study.

298 We also compute the surface LW cloud radiative effect for low clouds, which  
299 we call LW CRE\*, defined as the difference in surface downward LW flux with a low  
300 cloud present and with clear-sky conditions. A positive value of LW CRE\* indicates  
301 that low clouds have a warming effect on the surface. The asterisk is meant to  
302 remind the reader that we compute the surface LW cloud radiative effect at a point  
303 beneath a low cloud that covers the sky. In other words, if a low cloud suddenly  
304 passes overhead and covers the sky, then LW CRE\* is equal to the additional LW flux  
305 reaching the surface. LW CRE\* is generally not equal to the monthly mean LW CRE  
306 because only low clouds are considered in the calculation of LW CRE\* and, at a given  
307 point, low clouds will not obscure the sky for the entirety of the month. The  
308 calculations were performed without middle or high clouds in order to isolate the  
309 contribution to the surface energy budget made by low clouds.

310 We make several assumptions about low clouds in the calculations. We use  
311 satellite observations of LWP for the “open water” composite and use a wide range  
312 of liquid and ice cloud conditions for the “sea ice” composite where observations are  
313 not available. Low clouds are assumed to have a base at 0.5 km and a top at 1 km.  
314 Uncertainty in the LWP retrievals over the “open water” composite is less than 10  
315 g/m<sup>2</sup> for all observations considered and is typically ~4 g/m<sup>2</sup>. Uncertainty in LWP  
316 has a negligible effect on the computed surface downward LW flux because liquid  
317 clouds are nearly opaque to LW radiation for LWP values greater than ~20 g/m<sup>2</sup>,  
318 which is much lower than values observed over the Southern Ocean (Figure 7c)  
319 [Hartmann, 2016]. Low clouds over “open water” are assumed to consist entirely of  
320 supercooled liquid, which is a good approximation over the Southern Ocean [Hu et

321 al., 2010; Morrison et al., 2011], and have a droplet effective radius of  $16 \mu\text{m}$ , which  
322 is close to the observed wintertime mean over the Southern Ocean [McCoy et al.,  
323 2014, their Figure 9].

324 The clear-sky surface downward LW fluxes are significantly larger over  
325 “open water” than over “sea ice” because of the warmer, moister boundary layer  
326 (Figure 8). The average downward LW flux at the surface is  $24.4 \text{ W/m}^2$  larger over  
327 “open water” than over “sea ice” and the difference is significant at the 95%  
328 confidence level. In order to test the sensitivity of the surface downward LW flux to  
329 variations in humidity and temperature, the calculations were repeated with  
330 humidity fixed to mean values at each height and temperature varied, and vice  
331 versa. The clear-sky surface downward LW flux is slightly more sensitive to  
332 variations in temperature than to variations in humidity (not shown).

333 Low clouds make a substantial contribution to the surface downward LW  
334 flux. The mean surface LW CRE\* over the “open water” region is  $87.3 \pm 0.1 \text{ Wm}^{-2}$ ,  
335 which is a 44% increase over the clear-sky surface downward LW flux (Figure 8).  
336 The surface LW CRE\* is insensitive to variations in LWP because liquid clouds  
337 become nearly opaque to LW radiation at LWP values of  $\sim 20 \text{ g/m}^2$ , which is much  
338 lower than observed values over the “open water” composite (Figure 7c). The 95%  
339 confidence interval for the mean LW CRE\* over open water is therefore quite  
340 narrow and can hardly be seen in Figure 8b.

341 Differences in the mean boundary layer properties over the “sea ice” and  
342 “open water” composites can be used to compute the jump in surface downward LW

343 flux across the sea ice margin. Mean values for the quantities needed for this  
344 calculation are shown in Table 1.

345 The average surface downward longwave flux ( $LW_{\downarrow}$ ) can be expressed as the  
346 sum of the clear-sky flux ( $LW_{\downarrow, \text{clear}}$ ) and the additional surface downward LW flux  
347 contributed by a low cloud (LW CRE\*) multiplied by the frequency at which low  
348 clouds are observed (LCF):

349

$$350 \quad LW_{\downarrow} = LW_{\downarrow, \text{clear}} + LCF(LW \text{ CRE}^*).$$

351

352 This equation neglects the contribution of middle and high clouds to the surface  
353 energy budget. However, middle and high cloud fractions are much smaller than the  
354 mean LCF and are not significantly different between the “sea ice” and “open water”  
355 composites (not shown). If  $\Delta$  represents the difference of a quantity across the sea  
356 ice edge, then

357

$$358 \quad \Delta LW_{\downarrow} = \Delta LW_{\downarrow, \text{clear}} + \Delta LCF(LW \text{ CRE}^*) + LCF(\Delta LW \text{ CRE}^*) + O(\Delta^2).$$

359

360 In other words, the jump in surface downward LW flux across the sea ice edge is due  
361 to differences in clear-sky LW flux, low cloud frequency of occurrence, and radiative  
362 properties of low clouds. The first and second term on the right hand side, which  
363 correspond to the contribution from the difference in clear-sky LW flux and from  
364 differences in low cloud occurrence, are  $24 \text{ W/m}^2$  and  $15 \text{ W/m}^2$ , respectively. The  
365 third term, which is the contribution from differences in radiative properties of low

366 clouds across the ice edge, cannot be computed due to lack of observations of cloud  
367 liquid and ice water path over sea ice. However, the average surface LW CRE over  
368 the “open water” composite is at least as large, if not larger, than over “sea ice”  
369 (Figure 8b). Neglecting the contribution from higher order terms, it follows that the  
370 average surface downward LW flux is at least  $39 \text{ W/m}^2$  larger over the “open water”  
371 region than over “sea ice.” We emphasize that we have computed a lower bound  
372 estimate for the jump in average surface downward LW flux across the sea ice edge  
373 during winter. Our estimate accounts for differences in low cloud occurrence across  
374 the sea ice margin but not for differences in the radiative properties of low clouds. If  
375 low clouds over sea ice are more often composed of ice due to colder temperatures,  
376 or tend to hold less condensate because of their shallower depths (Figure 2b), then  
377 the true value for the jump in mean surface downward LW radiation may be on the  
378 order of 10’s of  $\text{W/m}^2$  larger than our lower bound estimate of  $39 \text{ W/m}^2$  (Figure  
379 8b).

380         Suppose that the clear and cold boundary layer that forms over sea ice was  
381 | able to persist over open water, so that heat loss from the ocean was  $\Delta LW_{\downarrow} = 39$   
382 |  $\text{W/m}^2$  larger. Assuming an ocean mixed layer of depth  $h_{ML} = 100 \text{ m}$  [Dong et al.,  
383 | 2008], this additional heat loss would cool the mixed layer at a rate of

384

$$\frac{dT}{dt} = \frac{\Delta LW_{\downarrow}}{c_p \rho_w h_{ML}}$$

385

386 | where  $c_p = 3985 \text{ J}/(\text{kg } ^\circ\text{C})$  is the heat capacity of seawater at  $0^\circ\text{C}$  and  $\rho_w = 1024$   
387 |  $\text{kg}/\text{m}^3$  is the density of seawater at salinity of  $30 \text{ g}/\text{kg}$ . Over a 30 day period, this  
388 | would result in a cooling of the mixed layer of  $0.25^\circ\text{C}$ . If this additional heat loss  
389 | were instead used to freeze new sea ice, it would cause a growth rate of:

390

$$\frac{dh}{dt} \approx \frac{\Delta LW_{\downarrow}}{L}$$

391

392 | which would result in  $0.34 \text{ m}$  of sea ice over a 30 day period. The strong greenhouse  
393 | effect of the convective boundary layer over open water therefore acts to slow heat  
394 | loss from the ocean and horizontal expansion of sea ice.

## 395 | **5. Southern Ocean winter low cloud in Global Climate Models**

396 | Accurate representation of marine boundary layer clouds and their radiative  
397 | effects has long been recognized as a major challenge for global climate models  
398 | (GCMs) [Dufresne and Bony, 2008; Trenberth and Fasullo, 2010]. We provide a brief  
399 | evaluation of several GCMs based on their ability to simulate the contrast in low  
400 | cloud amount across the sea ice edge. Both fully coupled and atmosphere only  
401 | (AMIP) configurations are analyzed between 1990-2004 [Taylor et al., 2012; Gates,  
402 | 1992]. Fully coupled models have prescribed radiative forcing from observations,  
403 | while AMIP models have prescribed sea surface temperature and sea ice  
404 | concentration from observations. Model climatologies are compared to the  
405 | climatology from observations taken between 2006-2014.

406 Figure 9 shows the JJA-mean 0.96–1.44 km cloud incidence and sea ice edge  
407 over the Southern Ocean for seven fully coupled CMIP5 models and observations.  
408 Model behavior is quite diverse; some models simulate slightly cloudier conditions  
409 over sea ice than over open water (i.e. the IPSL models) and others simulate a  
410 gradient in total low cloud fraction across the sea ice edge that is roughly a factor of  
411 three larger than observations (e.g. MIROC-ESM-CHEM and MIROC-ESM; Figure 11).  
412 Four of the seven fully coupled models simulate cloudier conditions over open  
413 water than over sea ice in the vicinity of the sea ice edge, with the two IPSL models  
414 and the MPI model being the exceptions. The MPI model does simulate a deeper low  
415 cloud layer over open water than over sea ice, but also simulates far too much cloud  
416 over sea ice in the lowest model layer (not shown). The IPSL models differ only in  
417 resolution and have very similar climatological profiles of LCF and the sea ice edge  
418 (Figure 9; Figure 11). Finally, it is interesting to note that in observations, the  
419 magnitude of the gradient in low cloud incidence across the ice edge at the 0.96-1.44  
420 km level is smallest in the Western Pacific and Southern Indian Ocean (20°E–160°E),  
421 and models do not capture this pattern.

422 Results from the atmosphere only models are shown in Figure 10. In this  
423 configuration, sea ice can influence the boundary layer above but not vice versa. All  
424 models except for CNRM-CM5 have a clear jump in cloud cover across the ice edge in  
425 the layer between 0.96-1.44 km, demonstrating the influence of sea ice on the  
426 boundary layer in models. Model bias in mean LCF across the ice edge is smaller in  
427 the atmosphere only models than in the fully coupled models (Figure 11),  
428 suggesting that problems with ocean models, sea ice models, or coupling between

429 the two and the atmosphere may contribute additional bias in low cloud. It will be  
430 useful to see if this is true for a larger set of GCMs when satellite simulator output  
431 for more models becomes available.

## 432 **6. Conclusions**

433 Active satellite retrievals from CALIPSO and in situ measurements show a  
434 strong contrast in low cloud amount and boundary layer structure over Antarctic  
435 sea ice and the adjacent open ocean during winter. Sea ice insulates the ocean,  
436 causing a cold, stable, dry and clear boundary layer to form over sea ice and a warm,  
437 cloudy, moist and convective boundary layer over open water. On average, the  
438 surface downward LW flux is at least  $39 \text{ W/m}^2$  larger over open water north of the  
439 sea ice edge than over sea ice to the south. The relatively strong greenhouse effect of  
440 the convective boundary layer that forms over open water slows cooling of the  
441 ocean mixed layer and sea ice growth compared to what would happen if the clear,  
442 dry boundary layer that forms over sea ice was able to persist over open water.  
443 Similarly, advection of moist boundary layer air from open water regions to sea ice  
444 covered regions slows sea ice growth.

445 These results support the hypothesis of two way interactions between the  
446 ocean surface and the atmospheric boundary layer during winter over high latitude  
447 oceans. Regions of open water have relatively warm surface temperatures and large  
448 surface fluxes of heat and moisture to the atmosphere. Moist, warm, and convective  
449 boundary layers with a strong greenhouse effect form over open water and thus  
450 reinforce the warm surface temperatures there. If such a region were to become

451 covered by sea ice then the surface heat and moisture fluxes would dramatically  
452 reduce and the boundary layer would cool, dry and radiate less LW down to the  
453 surface. This would reinforce the cool surface temperatures and allow the sea ice to  
454 persist. Interactions between the ocean, sea ice and the boundary layer have been  
455 proposed as a positive feedback in response to Arctic sea ice loss [Serreze et al.,  
456 2009; Kay and Gettelman, 2009; Screen and Simmonds, 2010], to influence natural  
457 variability in the present Arctic climate [Leibowicz et al., 2012] and as a mechanism  
458 to explain equable climates [Abbott and Tziperman, 2008]. Over the Southern Ocean  
459 during winter, interactions between the ocean, sea ice, and atmospheric boundary  
460 layer act to reinforce the relatively warm temperatures over open water and cold  
461 temperature over sea ice, and hence to stabilize the location of the sea ice edge.

462         Additionally, seven CMIP5 models with CALIPSO simulator output were  
463 examined. This work highlights the large differences in the mean profiles of low  
464 clouds over ocean in GCMs. We hope that the observed relationships shown here  
465 will be a useful test for future model intercomparison projects when CALIPSO  
466 simulator output for more models is available.

467

## 468 **Acknowledgements**

469           This research was conducted with support from NASA grant NNX14AJ26G,  
470 Terra and Aqua Science. Tsubasa Kohyama was supported by the National Science  
471 Foundation (NSF) under grant AGS-1122989, Takenaka Scholarship Foundation,  
472 Iizuka Takeshi Scholarship Foundation, and the NSF under grant AGS-0960497. We  
473 thank Steve Warren and Cecilia Bitz for helpful discussion and Peter Blossey for  
474 sharing the RRTMG code. We also thank the CALIPSO team for making the data  
475 readily available and the authors of [Chepfer et al., 2010] for creating the GOCCP  
476 dataset. We acknowledge the World Climate Research Programme's Working Group  
477 on Coupled Modelling, which is responsible for CMIP, and we thank the climate  
478 modeling groups for producing and making available their model output. For CMIP  
479 the U.S. Department of Energy's Program for Climate Model Diagnosis and  
480 Intercomparison provides coordinating support and led development of software  
481 infrastructure in partnership with the Global Organization for Earth System Science  
482 Portals.

## 484 **Appendix**

### 485 **Derivation of 95% confidence interval for the mean low cloud fraction**

486           The mean low cloud fraction (LCF) as a function of meridional distance from  
487 the sea ice edge for the Weddell Sea is shown in Figure 3b, Figure 12 and Table 1,  
488 and for the Ross Sea in Figure 3g. The 95% confidence interval for mean LCF was  
489 computed assuming that the LCF measured at each grid cell and time is  
490 independent. The LCF data is available as monthly averages on a  $2^\circ \times 2^\circ$  (longitude,  
491 latitude) grid. To justify the assumption that measurements of LCF at each grid cell  
492 and time are independent we must assess spatial and temporal autocorrelation.

493

#### 494• *Serial correlation in the meridional dimension*

495           Our goal is to bin the data by meridional distance from the ice edge and  
496 compute the mean and 95% confidence interval for the mean of each bin. The  
497 CALIPSO grid is resolved in  $2^\circ$  latitude grid cells, and when compositing by  
498 meridional distance from the ice edge we use bins of width  $0.5^\circ$  latitude. Therefore,  
499 for any given time, no two grid cells of the same longitude and neighboring latitudes  
500 can be assigned to the same bin. We therefore do not need to consider serial  
501 correlation in the meridional dimension when estimating the effective degrees of  
502 freedom of each bin.

503

#### 504• *Serial correlation in the zonal dimension*

505 We estimate a lower bound for the number of degrees of freedom in the  
506 zonal dimension by computing the correlation length scale  $L$  for each latitude and  
507 time, and comparing it to the resolution of the CALIPSO grid. Following [Taylor,  
508 1921; Keller, 1935], we define the correlation length scale as

509

$$L = \int_0^{\infty} r(\tau) d\tau$$

510

511 where  $r(\tau)$  is the spatial autocorrelation function of LCF in the zonal dimension and  
512  $\tau$  is the separation distance. The distance between independent points in the zonal  
513 dimension can be thought of as  $2L$ . For each time and latitude within 10 degrees of  
514 the sea ice edge we computed  $2L$ , and the maximum value was an order of  
515 magnitude smaller than the  $2^\circ$  longitude resolution of the CALIPSO grid. We  
516 therefore treat each grid cell as an independent measurement of LCF in the zonal  
517 dimension.

518

519• *Serial correlation in the time dimension*

520 Each longitude and latitude grid cell contains a timeseries of LCF  
521 observations, and the number of effective degrees of freedom of the LCF timeseries  
522 ( $N_{eff}$ ) is related to the number observations of LCF ( $N$ ) and the lag-1  
523 autocorrelation of LCF ( $r_1$ ) by the following equation [Bretherton et al., 1999]:

524

$$\frac{N_{eff}}{N} = \frac{1 - r_1}{1 + r_1}$$

525

526 Our goal is to bin the observations of LCF by their meridional distance from the ice  
527 edge and then to use this equation to estimate the effective degrees of freedom for  
528 each bin. For each longitude and latitude grid cell we compute  $r_1$  over the entire  
529 timeseries. Then, for a given bin, say “bin A,” and a given grid cell, say “grid cell B,”  
530 we keep track of the number of times that grid cell B is assigned to bin A and then  
531 compute an estimate for the number of effective degrees of freedom contributed to  
532 bin A by grid cell B by scaling by the right hand side of the above equation. This  
533 procedure was repeated for every grid cell and every bin.

534

535 The total number of effective degrees of freedom for each bin estimated by this  
536 procedure is slightly greater than if one were to assume each observation of LCF is  
537 independent in the time dimension. This happens because the lag-1 autocorrelation  
538 of LCF over the domain tends to be slightly negative. We therefore assume that each  
539 estimate of LCF is independent in the time dimension.

671 **Table Captions**

672 **Table 1.** Mean and 95% confidence interval for various observed and computed  
673 values over the “open water” and “sea ice” composites ( $1^{\circ}$ - $3^{\circ}$  equatorward and  $2^{\circ}$ - $4^{\circ}$   
674 poleward of the sea ice edge, respectively) during JJA in the Weddell Sea.  
675

676 **Figure Captions**

677 **Figure 1.** 2006-2014 climatology of June, July and August cloud incidence between  
678 0.96-1.44 km (color) and the 35% sea ice concentration contour (black line).  
679

680 **Figure 2.** (a) Map of region analyzed, (b) mean vertical profile of cloud incidence  
681 observed by CALIPSO, (c) mean SIC and mean and 95% confidence interval of LCF  
682 (see Appendix), and (d) mean vertical profile of potential temperature (contours)  
683 and specific humidity (color) over the Weddell Sea during JJA as a function of  
684 meridional distance from the ice edge. (e-h) as in (a-d) but for the Ross Sea.  
685

686 **Figure 3.** Cruise track and Ice Station Weddell (on which surface heat budget  
687 measurements were made) drift path during the period of study. The cruise  
688 traversed from west to east and the Ice Station Weddell drifted from south to north.  
689 The green dot shows the location of the sounding shown in Figure 5.  
690

691 **Figure 4.** Vertical temperature profile of the lower troposphere over the Weddell  
692 Sea during winter from soundings. For each height, color shows the probability  
693 density function of air temperature from soundings taken between 60-65°S (a) and  
694 poleward of 65°S (b). Bins of width 2°C were used in the calculation. The black  
695 dashed line shows a moist adiabat with a surface temperature of -1.8°C, the  
696 approximate freezing temperature of seawater in the Southern Ocean. Twenty-five  
697 soundings were used in both (a) and (b).

698

699 **Figure 5.** Observed low-level jets from soundings taken over the Weddell Sea. (a)  
700 One sounding showing an example of a low-level jet and inversion. See Figure 3 for  
701 the location at which this sounding was obtained. (b) Speed and direction of the  
702 low-level jet core for all observed jets.

703

704 **Figure 6.** Hourly-average measurements of the surface energy budget over a  
705 drifting ice floe in the Weddell Sea during April-May, 1992. Individual heat budget  
706 terms are shown in (a), including absorbed SW radiation ( $SW_{abs}$ ), surface latent and  
707 sensible heat fluxes ( $H_L$  and  $H_S$  respectively), upward and downward LW fluxes, and  
708 net heat flux. Terms are defined to be positive when heat flows into the ice. The box  
709 center line (edges) show the median (25- and 75-percentiles), while the whiskers  
710 show the 5- and 95-percentiles. The LW terms are shown in (b). The black line is the  
711 one-to-one line, while the red line and shading shows the mean and 95% confidence  
712 interval of the mean upward LW flux as function of downward LW flux. See text for a  
713 description of how this was computed.

714

715 **Figure 7.** Temperature (a), specific humidity (b), and LWP (c) values used in the  
716 radiative transfer calculations. Blue (gray) color denotes profiles from the “open  
717 water” (“sea ice”) composites. In (a) and (b), thick center lines show the mean value,  
718 while the edges of the dark (light) shading show the 25- and 75- (5- and 95-)  
719 percentiles at each height. LWP observations shown in (c) are from the “open water”  
720 composite.

721

722 **Figure 8.** Computed surface downward LW fluxes. Clear-sky fluxes for the “sea ice”  
723 (gray) and “open water” (blue) composites are shown in (a). The box center line  
724 (edges) shows the median (25- and 75-percentiles), and whiskers correspond to the  
725 5- and 95-percentiles. Surface LW CRE\* as a function of condensed water path is  
726 shown in (b). The mean and 95% confidence interval for all scenes in the “open  
727 water” composite are shown in blue. Values for low liquid and ice clouds over the  
728 “sea ice” composite are shown in dark and light gray, respectively. The light gray  
729 line (shading edges) shows the values for a liquid cloud with a droplet effective  
730 radius of  $16 \mu\text{m}$  (12-20  $\mu\text{m}$ ). The dark gray line (shading edges) shows the values  
731 for an ice cloud with ice crystal effective radius of  $30 \mu\text{m}$  (20-40  $\mu\text{m}$ ).

732

733 **Figure 9.** JJA-mean cloud incidence for the 0.96-1.44 km layer (color) and ice edge  
734 (contour) for seven fully coupled CMIP5 models with CALIPSO simulators and  
735 observations (“OBS”).

736

737 **Figure 10.** As in Figure 9 but for models in AMIP configuration. Note that only three  
738 models shown here also have output from their fully coupled configuration shown  
739 in Figure 9 (HadGEM2-A, MPI-ESM-LR, MIROC5).

740

741 **Figure 11.** Mean LCF during JJA in the Weddell Sea as a function of meridional  
742 distance from the sea ice edge for models in fully coupled and AMIP configurations  
743 and observations. Solid lines show models that have both fully coupled and AMIP  
744 output. Error bars on observations show the 95% confidence interval (see  
745 Appendix).

746

747 Tables

748

Composite	Surface $LW_{\downarrow, \text{clear}}$ ( $W/m^2$ )	Surface LW CRE* ( $W/m^2$ )	LWP ( $g/m^2$ )	CALIPSO LCF	Temperature/ Humidity
“open water”	$200.5 \pm 0.5$	$87.3 \pm 0.1$	$79 \pm 2$	$0.69 \pm 0.01$	See Figure 8
“sea ice”	$176.1 \pm 0.7$	-	-	$0.52 \pm 0.01$	

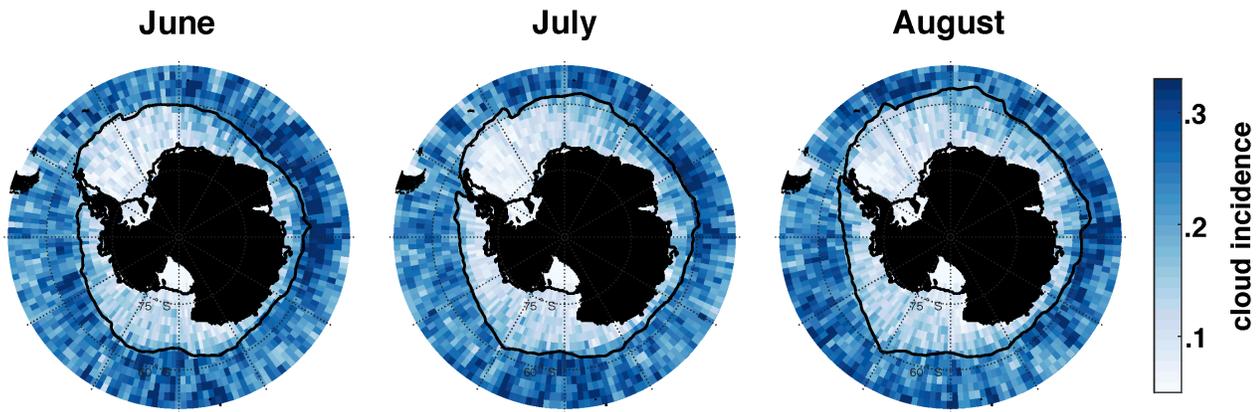

749

750 **Table 1.** Mean and 95% confidence interval for various observed and computed  
 751 values over the “open water” and “sea ice” composites ( $1^{\circ}$ - $3^{\circ}$  equatorward and  $2^{\circ}$ - $4^{\circ}$   
 752 poleward of the sea ice edge, respectively) during JJA in the Weddell Sea.
