**Evaluating the Lagrangian evolution of subtropical low clouds in GCMs using observations:
Mean evolution, timescales, and responses to predictors**

35 **Abstract**

36 A Lagrangian framework is developed to show the daily-scale time evolution of low
37 clouds over the Eastern Subtropical Oceans. An identical framework is applied to two General
38 Circulation Models (GCMs): the CAM5 and UKMET and a set of satellite observations. This
39 approach follows thousands of parcels as they advect downwind in the subtropical trade winds,
40 comparing cloud evolution in time and space. This study tracks cloud cover, in-cloud liquid
41 water path (CLWP), droplet concentration (N_d), boundary layer (PBL) depth, and rain rate as
42 clouds transition from regions with predominately stratiform clouds to regions containing
43 mostly trade cumulus.

44 The two models generate fewer clouds with greater N_d compared to observations.
45 Models show stronger Lagrangian cloud cover decline and greater PBL deepening compared to
46 observations. Comparing frequency distributions of cloud variables over time, models generate
47 increasing frequencies of nearly-clear conditions at the expense of overcast conditions, while
48 observations show transitions from overcast to cloud amounts between 50-90%. Lagrangian
49 decorrelation timescales (e-folding time, τ) of cloud cover and CLWP are between 11 and 19
50 hours for models and observations, though a bit shorter for models. A Lagrangian framework
51 applied here resolves and compares the time evolution of cloud systems as they adjust to
52 environmental perturbations in models and observations. Increasing subsidence in the
53 overlying troposphere leads to declining cloud cover, CLWP, PBL depth, and rain rates in models
54 and observations. Modeled cloud responses to other meteorological variables are less
55 consistent with observations, suggesting a need for continuing mechanical improvements in
56 GCMs.

57 **1. Introduction**

58 Extensive, warm, low clouds over the eastern subtropical oceans cool the surface by
59 reflecting sunlight while emitting infrared radiation (IR) at a temperature similar to the sea
60 surface. Changes in the properties of these clouds generate large impacts on local and global
61 temperatures (Klein and Hartmann, 1993; Ramanathan et al. 1989; Chen et al 2000). Much
62 effort has gone into understanding the drivers of variability in these clouds to improve their
63 representation in climate models. Currently, General Circulation Models (GCMs) do not
64 consistently simulate realistic low marine clouds, motivating further research into cloud
65 behavior in observations and models (Stephens, 2005). Here we apply a novel Lagrangian
66 approach to two climate models and a set of satellite observations to construct a comparison of
67 daily-scale cloud responses to environmental forcings.

68 Marine boundary layer clouds in the eastern subtropical oceans form in shallow decks of
69 stratocumulus (Sc) near the west coasts of major continents (Wood 2012). Here, the planetary
70 boundary layer (PBL) is a shallow layer of cool, humid air in contact with a cool sea surface,
71 below a strong temperature and humidity inversion separating the PBL from the relatively
72 warm, dry, and subsiding free troposphere. Air parcels at cloud top cool through upward IR
73 emission, then descend to the sea surface, driving a reciprocating rising. Offshore winds carry
74 these clouds into the tropics while many processes act simultaneously to modify them: Sea
75 surface temperatures (SSTs) warm, imparting latent heat and turbulence, deepening the PBL
76 enough that the radiatively-driven circulation no longer reaches the surface, decoupling the
77 cloud from its moisture source (Wyant et al. 1997). Dry air above the PBL entrains into the
78 cloud, evaporating cloud drops and warming the cloud (Mellado, 2017). Subsidence in the free

79 troposphere changes: A decrease in subsidence can drive PBL deepening and decoupling
80 (Eastman et al. 2017), while an increase may compress the PBL, lowering the trade inversion to
81 an altitude too shallow to maintain cloud cover within the PBL (Myers and Norris, 2013).
82 Varying moisture and temperature above the PBL modifies the radiative balance at cloud top
83 while altering the evaporative effects of entraining air (Eastman and Wood, 2018). Collision and
84 coalescence of cloud drops can reduce the number concentration of cloud droplets (N_d),
85 changing the cloud properties (Wood et al. 2018). Gravity waves propagating across the PBL
86 erode boundary layer clouds (Yuter et al. 2018). These processes act together on Sc, which are
87 eventually replaced by shallow cumulus (Cu) clouds as they advect into the tropics. This
88 simplified and incomplete list illustrates the challenges facing the modelling communities
89 attempting to create parameterizations in GCMs that simulate the cloud response to their
90 environment.

91 In Bony and Dufresne (2005), the climatological radiative response of clouds in the
92 tropics to an increase in SST was compared across 15 GCMs, showing inconsistent simulation of
93 shallow marine clouds. Agreement between models and observations was poorest, and the
94 spread between models was greatest, in tropical subsidence regions. This was substantiated by
95 a comparison of 32 models in the Coupled Model Intercomparison Project Phase 5 (CMIP5) by
96 Shin et al. (2017), who show a large inter-model spread in low cloud amounts. Qu et al. (2013)
97 show that the marine cloud response in models is more sensitive to SST than to inversion
98 strength. However, they stress that studying additional environmental variables is necessary.

99 Nam et al. (2012), comparing within CMIP5, show that models generate too-sparse and
100 too-optically thick clouds compared to observations. They introduce the term ‘too few, too

101 bright', characterizing the discrepancy, reported more currently by Berry et al. (2019) for the
102 CAM5 model. Karlsson et al. (2010) show that marine boundary layer depths are well
103 represented by models in Sc regions, but downstream there is more model spread and less
104 agreement with data, suggesting differences in parameterizations may be to blame for model
105 spread. Ceppi et al (2017) motivate a strategy to improve cloud behavior in GCMs by
106 introducing cloud resolving models into GCM grid boxes, creating so called superparameterized
107 models, and indeed Parishani et al (2019) have used such a model to examine the cloud
108 response to uniform SST increases, showing significant improvement in the simulation of the
109 vertical PBL structure. Additionally, the DYnamics of the Atmospheric general circulation
110 Modeled On Non-hydrostatic Domains (DYAMOND) project will use models which have a much-
111 improved 3km 'storm-resolving' resolution though they lack the horizontal resolution to resolve
112 PBL eddies. With improvement in computing power, these new models may improve GCM
113 quality, however coinciding observational comparisons will be necessary. This study introduces
114 a new comparison framework for models and observations that will allow for better testing of
115 these parameterizations, focusing on physical mechanisms driving cloud evolution and the
116 cloud system responses to those drivers.

117 Current studies comparing models to observations often compare averages over several
118 seasons or years, while not addressing day-to-day mechanics. deSzoeke et al. (2016) shows that
119 variability in satellite-observed cloud cover is greatest on multi-day, but sub-seasonal time
120 scales, and that the sensitivity of cloud cover to several environmental predictors varies
121 according to the timescales studied. Compositing techniques, such as those centered on fronts
122 and cyclones presented in Naud et al. (2019) show a great deal of promise in diagnosing model

123 processes, but they lack a time dimension, which can be used to compare model response
124 times to environmental changes. Eastman et al (2016) shows that e-folding times of cloud cover
125 and cloud liquid water along trajectories are only ~15-18 hours, suggesting cloud response to
126 environmental forcing is strongest on daily time scales. This motivates a new approach to the
127 study of cloud behavior that prioritizes day-to-day mechanics, which can act as a complement
128 to existing techniques and allow for a more complete systematic comparison.

129 Here we present a framework that can be applied to models and observations in order
130 to assess and compare the responses of cloud variables to environmental forcings on daily
131 timescales. This Lagrangian approach, sampling the same parcels as they evolve in time and
132 space, provides a time dimension, allowing for a more definitive look at cause-and-effect
133 relationships between clouds, their environmental controls, precipitation effects, and aerosol
134 indirect effects which manifest on timescales of hours-to-days. This framework also allows us to
135 compare the cloud response to an unprecedented number of predictors. This study focuses on
136 two GCMs, but future studies can incorporate many more models and predictors.

137

138 **2. Data**

139

140 *a) Models and observation sources*

141 Two GCMs are compared here: 1) the Community Atmosphere Model (CAM5), and 2) The
142 UK Met office model (abbreviated: UKMET, formally: Hadley Centre Global Environmental
143 Model (HadGEM)). For its physical parameterizations, the Fifth version of the Community
144 Atmosphere Model (CAM5 – Neale et al., 2010) uses the Morrison-Gettelman microphysics

145 scheme of Morrison and Gettelman (2008), the UW shallow cumulus scheme of Park and
146 Bretherton (2009), the turbulence scheme of Bretherton and Park (2009), the deep convection
147 scheme of Zhang and McFarlane (1995), and the RRTMG scheme for radiation (Mlawler et al.,
148 1997; Iacono et al., 2008). A horizontal resolution of $\sim 0.9 \times 1.25^\circ$ is used with 30 vertical levels.
149 The model is initialized on Jan. 1, 2008 based on ERA-I reanalysis and is left free-running for two
150 years, where the second year of hourly output (2009) is used for this analysis. Monthly SSTs are
151 prescribed by HadISST (Rayner et al. 2003).

152 The UKMET model is the Hadley Centre Global Environmental Model (HadGEM), based
153 upon the Unified Model. The configuration is a hybrid of that used for nested regional
154 simulations (mostly used for numerical weather prediction) and the HadGEM-UKCA
155 configuration used for climate modelling. The main atmospheric components are based on the
156 GA6.1 configuration (Walters et al. 2017) at version 10.3 of the Unified Model, including the
157 UKCA chemistry and aerosols package (Morgenstern 2009, O'Connor 2014).

158 Shallow, mid, and deep convection are parameterized separately in the UKMET from
159 large-scale cloud (Walters et al. 2017) and do not take into account aerosol or droplet number.
160 The large scale cloud microphysics scheme is based on Wilson and Ballard (1999), but with
161 improvements to the warm rain parameterizations (Boutle et al., 2014). The UKCA-Activate
162 scheme is used to produce cloud droplets from aerosol using the West (2014) scheme; this
163 utilizes the parameterization of Abdul-Razzak and Ghan (2000). The bulk properties (cloud
164 fraction, cloud liquid water content, vertical overlap, etc.) of large-scale cloud are
165 parameterized using the prognostic cloud fraction and prognostic condensate (PC2) scheme
166 (Wilson 2008a, Wilson 2008b) with modifications described in Morcrette (2012). The PBL is

167 parameterized using the turbulence closure scheme of Lock et al. (2000) with modifications
168 described in Lock (2001) and Brown (2008). For radiation, the scheme of Edwards and Slingo
169 (1996) is used with a configuration based on Cusack et al. (1998), but with a number of
170 significant updates as summarized in Walters et al. (2017). A horizontal resolution of
171 $\sim 1.875 \times 1.25^\circ$ (208 \times 139 km at the equator) is used. Seventy vertical levels are used between
172 the surface and ~ 70 km altitude.

173 The UKMET model is nudged every 6 hours to ERA-Interim horizontal wind fields between
174 ~ 2277 m and $\sim 47,251$ m to ensure that the real meteorology is approximately reproduced while
175 allowing fast-acting local boundary layer responses. Following the recommendations of Zhang
176 (2014), we do not nudge the temperature field in order to further allow the model to respond
177 more freely to induced local temperature changes. Instantaneous (non-time averaged) data is
178 output every 7 hours for the UKMET model. Monthly SSTs are prescribed by HadISST, as for the
179 CAM5.

180 Observational data come from three Afternoon Constellation (A-Train) satellites and the
181 ERA-Interim reanalysis (ERA-I, Dee et al. 2011). The A-Train is a series of sun-synchronous, polar
182 orbiting satellites flying in close formation, sampling the same scenes with a variety of sensors.
183 The A-train crosses the equator at $\sim 1:30$ and $\sim 13:30$ local time. Model sampling times and
184 locations along trajectories are determined by finding the time and place where the trajectories
185 would have been sampled by the sensors aboard Aqua. Output fields are then interpolated for
186 these times and locations.

187

188 *b) Lagrangian framework*

189 We compare the behavior of cloud variables as they evolve over 48-hours in the
190 boundary layer along Lagrangian trajectories, driven by the isobaric winds at 925 hPa produced
191 the models and the ERA-Interim reanalysis. Reanalysis winds are used for the observational
192 portion of this work. Model trajectories are generated using the same routine as for the
193 reanalysis winds, substituting model wind fields for reanalysis fields. Study regions include four
194 subtropical ocean basins, first described in Eastman and Wood (2016): The Northeast Pacific,
195 Southeast Pacific, Southeast Atlantic, and the East Indian oceans. The regions are chosen to
196 capture the maximum in Sc near the coasts and the downwind transition into trade Cu, as
197 shown by the climatological averages in Hahn & Warren (2007).

198 We use a subset of the trajectories introduced in Eastman and Wood (2018), where
199 ~160,000 48-hour forward-running trajectories were computed for 2007-2010. Here, only the
200 years 2009 and part of 2010 are compared. Each trajectory originates from an identical point in
201 the models and observations, chosen at 200-km intervals along the CloudSat/CALIPSO track in
202 order to assess 0-hour precipitation and PBL properties. For the Community Atmosphere Model
203 (CAM5), trajectories are run for the year 2009. For the UK Met Office model, trajectories are
204 run from March 2009-March 2010. Observational trajectories are chosen to overlap with both
205 sets of model trajectories, from January 2009 - March 2010. These time periods do not overlap
206 perfectly, so a test was performed comparing trajectories shared by all three platforms, which
207 showed no qualitative disagreement with the results from the larger sets. Comparisons
208 performed here are based on averages generated by compositing hundreds or thousands of
209 trajectories per platform, not comparing individual trajectories from the same origination point.
210 Cloud and predictor variable samples taken along trajectories include all grid-boxes with

211 centers within a 100-km radius from each sampling point for both models and observations. We
212 choose this uniform, coarse sampling to even out differences in grid box sizes in source data.

213 Composited mean trajectories from each model and the reanalysis are compared in
214 Figure 1. This compositing is done by subtracting the starting latitude and longitude from each
215 sample point along each trajectory, then calculating the mean location of all sample points at
216 each sample time within each region, then adding the mean start point from each region to the
217 mean trajectory. All three show comparable mean behavior, with trajectories curving from
218 equatorward to westward. Model trajectories are, on average, slightly longer than the
219 reanalysis trajectories. The geographical distributions of all trajectories from both models and
220 the reanalysis (not shown) show a consistent pattern between all three.

221 To compare the evolution of trajectories without biases introduced by geographic,
222 seasonal, or diurnal differences, anomalies are generated for all data at all observation times
223 and locations. Anomalies are calculated by subtracting the 100-day running mean at each
224 location sampled, centered on each day, for day and night separately.

225 Data are broken into two categories: Cloud variables, which describe the nature and
226 amount of cloud cover and depth of the PBL, and predictor variables, which may alter the
227 clouds through a variety of mechanisms.

228

229 *c) Cloud Variables*

230 Cloud variables are not just a measure of cloud cover, but also water content, droplet
231 concentration, PBL depth, and rain rate. Several of these variables can be measured using a
232 variety of instruments, or can be extracted from models using multiple techniques. Mean

233 values of these variables are to some extent driven by these procedural differences instead of
234 actual differences between the observations and models. This is an unavoidable drawback of
235 such a study until a truly uniform set of methods is developed, which will be necessary for
236 better comparisons in the future. Although mean values of cloud variables differ, these issues
237 are reduced when assessing Lagrangian change, since the change over time will have the
238 absolute value of a variable removed. For quick reference, observed cloud variables and their
239 sources are briefly described in Table 1, and described in detail below.

240

241 i) cloud cover

242 Cloud cover observations come from the Moderate Resolution Imaging
243 Spectroradiometer (MODIS) level-3 cloud mask product for total cloud cover during day and
244 night (Hubanks et al. 2008; Oreopoulos 2005) from the Aqua satellite. Data are available on a
245 $1^{\circ}\times 1^{\circ}$ grid. The wide view angle of MODIS causes a zenith angle bias where more cloud cover is
246 reported at wider angles (Maddux et al. 2010). This may cause an observation bias, so a zenith
247 angle correction is applied as described in Eastman and Wood (2016).

248 Cloud cover data from each GCM is based on the total cloud cover generated by the
249 models within each grid box. A satellite simulator, the Cloud Feedback Model Intercomparison
250 Project (CFMIP) Observation Simulator Package (COSP, Kay & NCAR, 2019) was tested for the
251 UKMET total cloud cover. Cloud amount produced by the COSP was correlated with raw cloud
252 amount, producing a correlation coefficient of $r=0.9$, meaning variability between the two is
253 nearly equivalent.

254

255 ii) Cloud Liquid Water Path

256 Observations of cloud liquid water path (CLWP) come from the Advanced Microwave
257 Scanning Radiometer for Earth Observing System (AMSR/E, Wentz & Meisner 2004), carried
258 aboard the Aqua satellite. The AMSR/E LWP values represent the total liquid water path (TLWP)
259 for $0.25 \times 0.25^\circ$ latitude-longitude grid boxes for both clear and cloudy portions. To provide a
260 measurement of in-cloud-only LWP (CLWP), TLWP values are averaged into $1^\circ \times 1^\circ$ boxes, then
261 divided by the MODIS cloud fraction in that box.

262 Liquid water path from AMSR/E may be biased by incorrect partitioning between rain
263 and cloud water (Seethala & Horvath, 2010, Lebsock & Su, 2014). Our AMSR/E CLWP values
264 were compared to those produced by MODIS for daytime-only observations (Platnick et al.,
265 2016), producing a correlation coefficient of $r = 0.64$ for co-located data points. We use the
266 AMSR/E here because data are available during both day and night. Data from the MODIS CLWP
267 product are used to show the variability between CLWP retrievals from different sensors, but
268 this data is not used in any other analyses.

269 Liquid water path is output from both GCMs as TLWP, then scaled by model cloud
270 fraction into CLWP. The CAM5 offers a single value of LWP, which may occasionally contain
271 convective clouds. A cloud top height filter was applied, excluding clouds above a range of
272 threshold values, and results were not sensitive to the exclusion/inclusion of occasional
273 convective elements. The UKMET LWP variable is assigned to the cloud-only LWP, excluding
274 rain water and deep convection.

275

276 iii) droplet concentration

277 Cloud droplet number concentration (N_d) is estimated using equation 1 from Eastman
278 and Wood (2016), which is corrected and shown here also as equation 1:

279

$$280 \quad N_{eff} = \sqrt{2} \frac{3}{4\pi\rho_\omega} \Gamma_{eff}^{1/2} \frac{LWP^{1/2}}{r_e(h)^3} \quad \text{Equation 1}$$

281

282 As in Eastman and Wood 2016: " ρ_ω is the density of liquid water; $\Gamma_{eff} = \Gamma_{ad} f_{ad}$; with Γ_{ad} as a
283 measure of the adiabatic rate of increase in liquid water content with respect to height;
284 constant f_{ad} is an estimate of the degree of adiabaticity; and h represents the cloud top height.
285 We then calculate droplet concentration with the relationship: $N_d = N_{eff}/k$, with k assumed to be
286 to 0.8 for marine stratiform clouds (Martin et al. 1994, Wood 2000)". Effective radius (r_e) and
287 LWP come from the daytime-only MODIS 3.7 μ m retrievals, so N_d is only reported during the
288 day.

289 Estimating N_d from satellite retrievals requires a significant number of assumptions
290 about the cloud properties (Fu et al. 2019). As for the CLWP mentioned above, two other N_d
291 datasets are compared in order to better show the uncertainty in observed N_d . One dataset
292 comes from Grosvenor & Wood (2018), which uses MODIS collection 5.1 optical retrievals and a
293 different set of assumptions compared to the product described above. The other comes from
294 the regressions described in McCoy et al. (2017) using aerosol concentrations from the
295 Modern-Era Retrospective Analysis for Research and Applications, Version 2 (MERRA-2, Galero
296 et al., 2017).

297 Cloud droplet number concentrations for cloudy portions of model grid boxes are
298 available for day and night from both models. Cloud-top N_d was derived from CAM5 output for

299 scenes with total cloud fraction greater than 20% and then taking the in-cloud N_d of the upper-
300 most grid box below 350hPa where the cloud fraction is greater than 20%. The CAM5 N_d is very
301 sensitive to the observation level within the cloud, in contrast to N_d behavior in most observed
302 clouds. This routine was necessary to produce physically reasonable CAM5 N_d values. For the
303 UKMET model a weighted vertical mean N_d was calculated, with the liquid water content on
304 each level used for the weights.

305

306 iv) boundary layer depth

307 Observed PBL depths (trade wind inversion height) come from Eastman et al. (2016 &
308 2017). These estimates use the difference between ERA-Interim SSTs and MODIS cloud top
309 temperatures (CTT) of a subset of clouds assumed to sit at the base of the trade inversion using
310 the algorithm described in Eastman et al. (2016). The routine is tuned using the vertical feature
311 mask product from the Cloud-Aerosol Lidar with Orthogonal Polarization (CALIOP) on the
312 Cloud-Aerosol Lidar and Infrared Pathfinder Satellite (CALIPSO, Vaughan et al. 2004) that is co-
313 located in space and time with the MODIS data. Maximum cloud top height (CTH) is also
314 calculated using this routine, but for the coldest cloud top within each box.

315 For the CAM5, PBL depth is estimated as the height below 11 km with maximum
316 vertical-gradient in potential temperature. The PBL depth from the UKMET is assigned to the
317 height at which RH declines most with increasing altitude as shown in Seidel (2010). An
318 approach more comparable to the observations was developed for the UKMET model, where
319 the cloud tops of boundary layer clouds were assumed to rest at the inversion (as diagnosed by
320 the model boundary layer scheme), and this produced a comparable result to the RH method,

321 correlating with an R value above $r = 0.95$. Cloud top heights in the CAM5 contained too many
322 outliers above 3km to attempt a similar comparison, so the potential temperature gradient
323 method is used instead.

324

325 v) Precipitation

326 Observed precipitation rate estimates (Average rain rates, Eastman et al. 2019) come
327 from AMSR/E 89 GHz brightness temperatures (T_b , Wentz and Meissner 2004; Ashcroft and
328 Wentz 2006), tuned using CloudSat Rain-Profile rain rates (Stephens et al. 2008; L'Ecuyer and
329 Stephens 2002; Lebsock and L'Ecuyer 2011), AMSR/E column water vapor (CWV) observations
330 (Wentz and Meissner 2004), and ERA5 SSTs and wind speeds (Copernicus Climate Change
331 Service, 2017). The routine from Eastman et al. 2019 was updated for year 2009. This routine
332 relies on the positive relationship between rainfall and warm T_b (Miller and Yuter, 2013) and
333 estimates rain rates from T_b after controlling for confounding variables: SST, CWV, and wind
334 speed.

335 Precipitation rates in both models are area-average rain rates within each sample. Some
336 UKMET rain rates exceeded the maximum observed rate by several mm/hr. These rates may be
337 an unrealistic model value, or it is possible that the T_b -derived rain rates are not sensitive to
338 rain rates above ~ 3 mm/hr. In order to improve comparability, UKMET rain rates exceeding the
339 maximum observed rate of 3.1 mm/hr were removed from the analysis, which resulted in the
340 exclusion of less than 0.06% of observations. Rain rates from AMSR/E tuned by CloudSat may
341 also lack sensitivity to extremely light drizzle, or very small cells that do not fill a pixel. This may

342 bias observed rain towards heavier-precipitating events, but is currently unavoidable given the
343 difficulty in retrieving drizzle rates from satellites.

344

345 *d) predictor variables*

346 Specific humidity above the PBL is taken at 700 hPa (q_{700}) in both models and in ERA-
347 Interim. Lower Tropospheric Stability (LTS) is the difference in potential temperature (θ)
348 between the surface and 700 hPa in both models and in ERA-Interim. Observed SST comes from
349 the surface skin temperature in ERA-Interim. For the UKMET and CAM5, SST is set to the
350 surface skin temperature, which changes smoothly based on monthly SST data from HadISST
351 (Rayner et al. 2003). Wind speed (WSP) is defined as the 10-meter wind speed, different from
352 the 925 hPa winds driving the trajectories. Ten-meter wind speed was not output in this CAM5
353 version, which instead offers a wind speed at ~60 meters. The 10-meter winds are estimated
354 using a power law relationship assuming minimal surface roughness and neutral stability,
355 shown in equation 2

356

$$357 \quad V_{10m} = V_{60m} \left(\frac{1}{6}\right)^P \quad \text{Equation 2}$$

358

359 The wind profile power law exponent P is assumed to be $1/7$ (Touma, 1977). V_{10} and V_{60} are
360 wind speeds at 10 and 60 meters, and the ratio between the lower and upper altitudes is $1/6$.

361 Subsidence is defined as the pressure velocity at 700 hPa (ω_{700}) for all platforms. Positive ω_{700} is
362 motion moving downward.

363

364 **3. Methods & Results**

365 *a) Mean Lagrangian evolution*

366 The 48-hour Lagrangian evolution of cloud variables are composited in Figure 2. Plots
367 represent the mean of all trajectories in all regions for each platform. The vertical width of each
368 plot represents the 2- σ standard error of the mean. Models produce less cloud cover than
369 observations (Figure 2a), especially the CAM5. Both models show stronger Lagrangian cloud
370 declines than the observations. The MODIS COSP satellite simulated UKMET cloud cover (not
371 shown) produces less daytime cloud cover than the UKMET output cloud variable, suggesting
372 that the true discrepancy between models and observations may be greater. This is likely due
373 to the MODIS instrument missing some small and optically thin clouds. In Figure 2b the UKMET
374 shows more CLWP and the CAM5 shows less than the AMSR/E product used here, though all
375 three show an increase over time. Light gray uncertainty bounds on the observed CLWP plot
376 represent the range of CLWP values produced by the AMSR/E and MODIS, showing a great deal
377 of uncertainty for the absolute values of observed CLWP. Figure 2c shows consistent Lagrangian
378 declines in N_d , with the CAM5 and UKMET producing similar N_d , while observations show less.
379 The light gray error bounds again represent the variability in the absolute values of N_d based on
380 the spread of N_d values produced by the method shown here, the Grosvenor & Wood (2018)
381 N_d , and the McCoy et al. (2017) MERRA-derived value. These wide bounds show a great deal of
382 uncertainty, and suggest that the modeled N_d values fall within the uncertainty bounds
383 produced by these differing methods. The observed PBL is deeper than the CAM5 (Figure 2d),
384 but shallower than the UKMET. Maximum CTH is significantly higher in the CAM5 than in the
385 observations or UKMET, suggesting CAM5 clouds are less sensitive to the inversion, causing

386 excess vertical cloud development instead of horizontal spreading. Modeled PBL depth exhibits
387 more Lagrangian deepening compared to the observations. Rain rates (Figure 2e) are heavier in
388 the CAM5 than in the observations or UKMET. Rain rates increase in both models and the
389 observations, though more strongly in models. Overall, modeled clouds tend to be less
390 extensive and prone to more Lagrangian deepening with stronger increases in rain rates
391 compared to observations.

392 In Figure 3 we compare the mean 48-hour evolution of predictors in the same fashion
393 as Figure 2. Average winds tend to increase slightly in the middle of our trajectories (Figure 3a),
394 then subsequently decline. This wind speed maximum at 24 hours is stronger for the ERA-I,
395 hinting at a possible sampling bias for the observations. However, a diurnal and regional
396 breakdown of these mean winds showed this signal was consistent between regions and for
397 day and night separately. Maps of ERA-I annual mean wind speed show maxima near the
398 downwind edges of our grid boxes, so it is likely that many trajectories are passing through
399 these maxima. The increase in CLWP and rain rate and the decline in N_d at 24-hours in Figure 2
400 may be associated with this wind speed peak, perhaps through modified surface fluxes. Figure
401 3b shows Lagrangian increases in q_{700} for all three plots. The UKMET is drier compared to the
402 nearly equivalent ERA-I and CAM5. The evolution of ω_{700} (Figure 3c), shows the UKMET as an
403 outlier with greater subsidence, despite having the deepest PBL. All three show equivalent
404 Lagrangian declines in subsidence. The Lagrangian evolution of LTS (Figure 3d) shows declines
405 over time for all three curves, and equivalent stability between the ERA-I and UKMET, while the
406 CAM5 is less stable. In Figure 3e SSTs show nearly identical increasing behavior, though the
407 ERA-I shows less of an increase.

408 A regional breakdown of mean Lagrangian evolution was performed to look for
409 systematic regional biases in models and to see if the differences in mean Lagrangian behavior
410 seen above are due to disagreements everywhere, or just in one region. For the most part,
411 regional variability matched between models and observations with a few exceptions. The PBL
412 in the CAM5 is much deeper than observations in the E Indian, but shallower in the SE Pacific
413 and SE Atlantic. Generally, both model PBLs were deeper and rainier in the E Indian compared
414 to observations. Comparing N_d , the CAM5 has higher N_d in the SE Pacific, perhaps overdoing
415 biomass burning effects there, while the UKMET shows greater N_d in the NE Pacific. Overall,
416 differences are most apparent for droplet concentrations and PBL depths, suggesting that
417 models may have a weaker grasp on those processes.

418 Normalized frequency distributions of cloud variables are compared at different
419 observation times along trajectories in Figure 4. Distributions are plotted for each variable at
420 three times for all of our trajectories in all regions at T= 0, 24, and 48-hours. Distributions are
421 normalized between 0 and 1 individually for all three sampling times in order to compare the
422 evolution of the shapes of the distributions. Differences are most striking for cloud cover,
423 where both models generate bi-modal distributions, with peaks at around 10% and 100%. In
424 contrast, the observed cloud cover distribution shows a single peak at the overcast end of the x-
425 axis. In observations, the cloud cover distribution gradually shifts from overcast towards broken
426 cloud cover over time, while in models the distribution shifts from overcast to cloud-free.
427 Distributions of CLWP appear similar for all three, though slimmer for the CAM5 and wider for
428 the UKMET. Droplet concentration distributions appear similar for both models and
429 observations, with a single peak, shifted to the right at earlier times. Distributions of PBL depth

430 show more Lagrangian deepening for the models compared to the observations, but all show a
431 single peak between 1-2 km. For all three platforms, rain rates are usually light with fewer cases
432 of heavier rain.

433 Differences in the mean values and Lagrangian evolution of cloud variables between
434 models and observations could be explained by a few things. Model variables may be
435 responding too quickly to environmental controls, or cloud variable sensitivity to those controls
436 may be too strong or too weak. The following analyses will test for these possibilities using this
437 Lagrangian framework.

438

439 *b) Time scales of cloud variables*

440 As clouds evolve following the flow, they are constantly adjusting to perturbations
441 within and surrounding the PBL. Using a Lagrangian framework it is possible to quantify the
442 adjustment times of cloud variables by comparing initial values to subsequent values at a later
443 time. If adjustment timescales of cloud variables are vastly different between models and
444 observations, models may be modifying clouds too quickly or too slowly as the clouds respond
445 to their environment. Disparities in these adjustment timescales could be the cause for
446 differences in the mean behaviors of cloud variables shown above. Here we test for this by
447 comparing characteristic adjustment timescales for cloud variables in models and observations.

448 These timescales are first explored in Eastman et al. (2016), where cloud variable
449 anomalies (CVAs, as defined in section 2) at later hours are plotted as a function of their 0-hour
450 values. That work shows that, on average, the evolution of anomalies of cloud cover, LWP, N_d ,
451 and PBL depth can be modeled as a red noise process with a persistent characteristic

452 decorrelation timescale: the e-folding time (τ), defined as the time (in hours) that it takes for
453 the lag autocorrelation to decline by a factor of $1/e$, and is estimated using Equation 3:

454

$$455 \quad \tau = \frac{-T}{\log[r(t)]} \quad \text{Equation 3}$$

456

457 Where T is the observation time along the trajectory (T=12, 24, 36, and 48 hours), and $r(T)$ is
458 the slope of a line fit to the plot of anomalies at later observation times (y-axis) as a function of
459 the 0-hour anomalies (x-axis). In Eastman et al. (2016) values of τ were on the order of 12-24
460 hours depending on the variable, showing that CVAs following the flow evolve and respond to
461 environmental perturbations most strongly on daily to sub-daily timescales. In Figures 5-7 we
462 apply that analysis (Eastman et al. 2016, their Figures 6-7) to observed and modeled cloud
463 variables.

464 Figures 5-7 are made by binning trajectories by their 0-hour CVA into six quantiles (x-
465 axis). The mean CVAs for those quantiles after they evolve along their trajectories are shown on
466 the y-axis as a function of their 0-hour values. For each time T, lines are fit to the plots using a
467 linear regression. Values of τ are calculated using Equation 3 and the slope of each line. As in
468 Eastman et al. (2016), plots for each observation hour are generally linear, though more-so for
469 observations than the models.

470 For the CAM5 (Figure 5), cloud cover and CLWP behave similarly (5a & b), with τ
471 increasing over time from ~ 12 to ~ 18 hours between T=12 and T=48. Values of τ are longer for
472 N_d , PBL depth, and rain rate. N_d shows longer τ at later observation times, ranging from 35
473 hours to 77 hours, while PBL depth τ increases with observation time from 21 to 27 hours. Rain

474 rates in the CAM5 have a stronger memory at short timescales, with more signal loss at later
475 observation times.

476 UKMET timescales are shown in Figure 6. Timescales for cloud cover and CLWP are again
477 similar to each other and to the CAM5, with τ increasing from ~ 10 to ~ 18 from $T=12$ to $T=48$.
478 Timescales for N_d and PBL depth are longer, with τ for N_d between 15-29 hours and τ for PBL
479 depth somewhat longer, between 23-35 hours. The precipitation plot appears very noisy with a
480 great deal of uncertainty at times beyond $T=12$. Rain rates appear to have long memories, but
481 these large numbers appear skewed by a batch of strongly negative initial anomalies that do
482 not diminish in time. In frames a, b, and d the UKMET shows a tendency for initial anomalies on
483 the far end of the negative side to damp out more quickly, skewing the left sides of the plots
484 upward and driving greater uncertainty in the fits. This behavior indicates a tendency in the
485 UKMET to too-quickly damp out negative extremes in cloud fraction, PBL depth, and CLWP.

486 Timescales for observed CVAs are compared in Figure 7. Once again, timescales are
487 shortest for cloud cover and CLWP, increasing from around $\tau=12-14$ to $\tau=20-21$ hours from
488 $T=12-48$ hours. For N_d , PBL depth, and rain rate, timescales are longer and increase with longer
489 T . Droplet concentration anomalies show τ values between 22-25 hours, while PBL depth shows
490 τ from 16-25 hours and τ for rain rates between 16-21 hours.

491 A comparison of τ at 24 hours for all variables is shown in Table 2. Adjustment
492 timescales for cloud cover and CLWP in models and observations are reasonably comparable,
493 evolving significantly within a diurnal cycle. However, there is a tendency for cloud cover and
494 CLWP in models to evolve more quickly than for observations. These slightly shorter τ values
495 hint at a faster cloud response to evolving environmental forcings in models. This could possibly

496 explain the faster Lagrangian declines in cloud cover in figure 2. However, this logic fails to
497 explain the more extreme Lagrangian PBL deepening in models since τ values are longer for
498 modeled PBL depth, suggesting that modeled PBL depth evolves more slowly on average.
499 Differences in mean climatological PBL depth behavior may instead be explained by differing
500 sensitivity to environmental forcing. Values of τ for rain rate in both models are longer than in
501 the observations, and the CAM5 τ for N_d is also very long, indicating deficiencies in model rain
502 and microphysical behavior.

503

504 *c) Effects of Predictor Variables*

505 Cloud evolution can be conceptualized as an internal mechanical system adjusting to a
506 changing environment. Given the ~12-36 hour timescales shown above, the strongest variability
507 in this system is on the order of a single diurnal cycle for both models and observations. Clouds
508 travel hundreds of kilometers in a day, so a Lagrangian framework is necessary to track cloud
509 processes while they occur. In this section we compare observed and modeled cloud responses
510 to predictors while following the flow for one day.

511 Predictor variables are selected based on how they can act to modify the clouds and the
512 PBL: subsidence acts to press downward on the PBL from above; humid air in the free
513 troposphere emits downwelling IR onto the PBL and mixes into the cloud top through
514 entrainment; LTS modulates entrainment across the inversion through buoyancy differences;
515 changes in SST modify latent and sensible heating into and out of PBL; surface winds mix this
516 heating into the clouds and drive small-scale turbulent circulations. These processes do not all
517 act on the clouds at the same speed, so a test was performed to see whether the initial (0-hour)

518 values or the 24-hour Lagrangian changes in predictor variable anomalies (PVAs) drove a more
519 powerful CVA response for the observations. Results showed that the 24-hour $\Delta\omega_{700}$ and 24-
520 hour ΔSST were stronger drivers of CVA variability than their 0-hour values, but for all other
521 predictors their 0-hour values were stronger. Therefore, we use the coinciding 24-hour
522 Lagrangian changes in SST and subsidence anomalies as predictors instead of their initial values.
523 Internal cloud processes involve several variables adjusting in concert and modifying one-
524 another, so CVAs are also tested as predictors to show a more complete picture of how clouds
525 respond to their environment and to internal perturbations.

526 This analysis combines 24-hour trajectory segments containing both day-to-day and
527 night-to-night changes and also combines different regions. To avoid biases associated with
528 combining these trajectories, PVAs and CVAs are used instead of raw values.

529 To test the effects of predictors, trajectories are subsetted by PVA value into σ bins: -
530 $2 < \sigma < -1$, $-1 < \sigma < 0$, $0 < \sigma < 1$, and $1 < \sigma < 2$. We use σ bins in order to compare the power of predictors
531 to one another (e.g. we can compare the change in cloud cover driven by a $1-\sigma$ difference in LTS
532 to the change driven by a $1-\sigma$ difference in $\Delta\omega_{700}$). The mean 24-hour Lagrangian change in the
533 CVA (ΔCVA , defined as: $\text{CVA}_{24} - \text{CVA}_0$) is then calculated for all trajectories within each σ bin.

534 The ΔCVA is broken into two components as in Eastman et al. (2017) and Eastman and
535 Wood (2018). 1) the change driven by the predictor variable being tested. 2) The change driven
536 by the red noise behavior seen in the prior section and described in Eastman et al. (2016).
537 Section 3b shows that CVAs tend to predictably damp out over time, so a group of trajectories
538 with a mean positive CVA at hour 0 will show a negative change over time, basically a
539 regression to the mean. When we subset trajectories based on predictors, the mean 0-hour

540 values of CVAs tend to be non-zero (e.g. a set of trajectories with high 0-hour LTS will begin
541 with above-average 0-hour cloud cover). The subsequent mean change in the cloud variable will
542 then be driven by the predictor and by the tendency to regress to the mean. We isolate the
543 change in the CVA driven by the predictor by calculating a residual change, where the change
544 driven by regression to the mean is predicted based on the linear relationships shown in 3b,
545 and is then subtracted from the ΔCVA .

546 Residual ΔCVA values are produced for each of the four σ bins and the slope of the four
547 points is estimated using a linear regression. This slope represents the mean change in CVA
548 forced by the PVA, independent of red noise. Each predictor variable is tested while another is
549 held constant in bins. The range of slopes produced while holding each other predictor constant
550 produces the uncertainty bounds on the slope. Examples of these slopes are shown in Figures 8
551 and 9, where the 24-hour residual cloud cover change forced by each predictor is shown for the
552 models and observations. These results are reiterated in Figure 10 and expanded for all
553 predictors.

554 The slopes in Figure 8 suggest fairly small cloud cover responses to internal cloud
555 variables. Figures 8a and 8c show that cloud decline may be associated with high CLWP and
556 deeper PBLs in both models and observations. The PBL depth appears to be the most consistent
557 predictor, particularly in observations where the entire range of slopes is negative, agreeing
558 with the conclusions of Eastman and Wood (2016), which showed that cloud cover declines in
559 deep PBLs. Ranges of slopes in both models are wide, indicating more uncertainty depending
560 on what is being controlled for.

561 Figure 9 shows the cloud cover response to meteorological predictors. Here, agreement
562 is seen in frames 9b and c where clouds in both models and the observations decline
563 significantly with increasing ω_{700} and drier q_{700} . Ranges of slopes are all positive in 9b and all
564 negative in 9c, suggesting a great deal of confidence there. Frames 9a and d show that clouds in
565 observations and the UKMET respond positively to stronger surface winds and LTS, while the
566 CAM5 clouds appear less sensitive. Frame 9e shows that both models generate cloud increases
567 when SST increases, but observed clouds show a weak response.

568 The results from Figures 8 and 9 are reiterated in Figure 10, which represents slopes as
569 bar plots. A positive CVA response to a positive PVA is shown by a bar plot pointing to the right,
570 while a negative response is shown by a bar pointing left. The ranges of slopes shown by the
571 shaded regions of Figures 8 and 9 are shown by horizontal error bars. Figure 10 shows the
572 responses to predictors for cloud cover, CLWP, N_d , PBL depth, and rain rate anomalies. Values
573 of σ (the denominator in the slope calculation) vary between the three platforms. In order to
574 improve equivalence the mean value of σ from all three platforms is used here in the
575 calculation of these slopes, allowing for direct comparison.

576 Figure 10 presents a great deal of information, so is broken down here by *cloud-*
577 *modifying-mechanism*. This allows for a systematic comparison of models and observations
578 focused on cloud system processes responding to environmental forcings.

579

580 *i) Subsidence*

581 Increasing subsidence presses the PBL top downward, reducing PBL depth. This thins
582 existing clouds, as seen by reduced CLWP, and completely dissipates some clouds by pressing

583 the inversion height down below the LCL as shown by the cloud cover response. Models and
584 observations agree on this so far, however the N_d response is different between models and
585 observations: N_d increases in models with increasing subsidence, while it decreases in the
586 observations. This could be an observational issue because thinner, patchier clouds may have
587 more cloud edges in the observation, biasing the N_d low. Conversely, models may overdo the N_d
588 increase due to inadequate parameterizations. Strong rain declines are seen with increasing
589 subsidence in the models. These strong rain responses may have to do with the long
590 decorrelation timescales of model rain. The 24-hour change in rain rate anomaly predicted by
591 red noise in models is small, so a moderate change driven by subsidence may produce a larger
592 residual. Somewhat narrow error bounds on the strong rain response to subsidence shows that
593 rain sensitivity to subsidence occurs independently of other variables, suggesting a somewhat
594 direct rain-subsidence relationship which invites additional scrutiny.

595

596 *ii) PBL deepening driven by radiative cooling*

597 The PBL response to a dry overlying troposphere is different between models and
598 observations. Observations here and in Eastman and Wood (2019) show that the PBL deepens
599 in response to a drier overlying troposphere, as shown by low q_{700} . This deepening is driven by
600 increases in radiative cloud top cooling, which enhances turbulence and entrainment. Both
601 models miss this mechanism, instead showing little PBL sensitivity to q_{700} . This may explain why
602 both models over-deepen the PBL offshore. If the effects of q_{700} , which increases offshore and
603 acts as a brake on PBL deepening, are neglected, clouds will deepen too quickly in the models.
604 The discrepancy may be driven by the reduced cloud cover in the models. Fewer clouds means

605 less surface area emitting IR upward, limiting upward IR flux and reducing cooling and
606 turbulence at PBL top.

607

608 *iii) Entrainment system*

609 The cloud response to higher q_{700} above the PBL is positive in both models and
610 observations. This is likely due to the increased entrainment of water vapor causing less
611 evaporation of cloud drops at cloud top. The unanimous, corresponding increase in CLWP
612 supports this, along with increased rain.

613 Inversion strength also modifies entrainment. Strong inversions are associated with
614 more cloud cover in the observations and UKMET. Both models and observations show that
615 high LTS is associated with less PBL deepening, lower CLWP, and lighter rain. This suggests that
616 the inhibition of entrainment caused by high LTS leads to slower Lagrangian evolution of cloud
617 variables. The CAM5 is an outlier here, showing little cloud cover sensitivity to LTS, which may
618 help to explain the significantly lower CAM5 cloud cover in these regions of climatologically
619 high stability.

620

621 *iv) Cloud microphysics and precipitation*

622 High N_d , which coincides with smaller cloud drop effective radii, inhibits precipitation
623 and leads to persistent clouds (Albrecht et al., 1989; Christensen et al. 2020). Observations here
624 show this, with a negative rain rate response to high N_d and a small corresponding cloud
625 increase. Results show that the cloud response to this system is less powerful compared to
626 some of the others discussed here, but this microphysical mechanism is resolved by the

627 observations. This process is not well simulated in the models, which show little cloud
628 sensitivity to N_d when following the flow. The CAM5 appears to see a decline in precipitation
629 associated with increased N_d , but the rest of this system is absent. Overall, this appears to be an
630 area where models are underperforming. This is surprising, in particular, because previous
631 studies have indicated that the LWP response to aerosols is likely overestimated in climate
632 models (Wang et al., 2012). Additionally, Grosvenor and Carslaw (2020) use a newer version of
633 the UKMET and show that additional aerosol suppresses precipitation and increases clouds in
634 the North Atlantic, though that work did not study Lagrangian change as done here. As
635 mentioned in section 3ci above, this motivates a closer look at model precipitation processes.

636

637 *v. Boundary layer decoupling*

638 The cloud top-to-sea surface circulation is often decoupled in deeper PBLs, cutting off
639 the direct supply of moisture and cloud condensation nuclei to the cloud layer, causing clouds
640 to thin and dry. Observations show this effect with declines seen in cloud cover, N_d , rain rate,
641 and CLWP for trajectories starting in deeper PBLs. The UKMET sees a similar cloud and N_d
642 response, but the CLWP increase in deep PBLs is opposite to the observations. The CAM5
643 produces cloud declines in deeper PBLs, but the N_d and CLWP both appear opposite to the
644 observations, suggesting an incorrect mechanism linking PBL depth and cloud cover evolution
645 there. The CLWP response to deep PBLs is inconsistent between models and observations here,
646 and also shows a great deal of uncertainty. This suggests that models do not properly
647 reproduce the changes in moisture flux into the cloud layer driven by PBL height/decoupling,

648 possibly indicating shortcomings in simulating thermodynamic processes and lapse rates in the
649 PBL.

650

651 *vi. Fluxes from surface winds and SST*

652 Stronger wind blowing over warming SST increases moisture and turbulent fluxes in the
653 PBL, invigorating and thickening clouds, and deepening the PBL. All three platforms agree that
654 CLWP is enhanced and the PBL deepens with stronger winds, but models show more PBL
655 deepening compared to observations, while observations show greater increases in cloud
656 cover. A likely explanation is that in models strong winds drive more PBL deepening, so the
657 thicker clouds become more vertically extensive, rather than more horizontally extensive as in
658 the observations.

659 The cloud cover and N_d responses to Δ SST are strong and positive for both models, but
660 nearly zero for the observations, suggesting the Δ SST is responsible for a greater share of
661 surface fluxes in models than in observations. The PBL deepens in response to a warming SST in
662 the observations and UKMET, but the response leans negative with much uncertainty in the
663 CAM5. Taken together, these analyses suggest that fluxes driven by winds and SST manifest
664 differently in models versus the observations. Modeled cloud cover appears oversensitive to
665 SST changes and under-sensitive to wind speed, while observations show that Δ SST mainly acts
666 on PBL depth with wind speed driving changes to cloud extent.

667

668 **4. Discussion**

669

670 *a) Model cloud processes and mean behavior*

671 Overall, results above suggest that these models tend to reproduce the subsidence and
672 entrainment-of-humidity mechanisms well. However, the rain rate response to changing
673 subsidence appears overdone in models, which may explain their stronger mean Lagrangian
674 increase in rainfall, possibly overreacting to the mean decline in subsidence. The UKMET
675 successfully simulates the effects of LTS on cloud variable evolution, though still shows less
676 cloud cover sensitivity than observations. Cloud cover in the CAM5 shows no sensitivity to LTS.
677 The weaker or nonexistent sensitivity of modeled clouds to LTS may explain the reduced cloud
678 cover in these study regions, which are characterized by strong inversions. Further, the stronger
679 Lagrangian reduction in model cloud cover could be explained by the lack of sensitivity to LTS
680 and to faster characteristic timescales, allowing modeled cloud variables to evolve more
681 quickly.

682 These results showing strong cloud declines associated with increased subsidence add
683 to those from Myers and Norris (2013), which show that clouds are less extensive with
684 enhanced subsidence when LTS is kept constant. This work shows that model clouds respond to
685 subsidence changes quickly and strongly, indicating that the downwind gradient of subsidence
686 will be of great importance to cloud evolution along with the mean value of subsidence. New
687 studies should take into account the changing subsidence gradient in these regions. It is
688 encouraging that both models simulate the subsidence system well, adding credibility to the
689 cloud response to weakening subsidence in global warming scenarios. Improvement in the LTS-
690 cloud relationships motivated here should further aid in simulating the cloud response to global
691 warming.

692 Differences between the Lagrangian evolution of CLWP between the models and
693 observations are apparent in Figure 2, where the UKMET shows significantly more CLWP, but
694 less cloud cover than the observations. The results of Figure 10 show that UKMET CLWP is much
695 more sensitive to nearly all predictors compared to the CAM5, and to some extent more
696 sensitive than the observations. This hints at a system in the UKMET that tends to strongly
697 modify cloud water, but not cloud extent. The CAM5 CLWP, meanwhile, tends to be less
698 sensitive to predictors than the UKMET or observations, and also shows the least CLWP in
699 Figure 2.

700 Models are less consistent with observations for a variety of other mechanisms. Both
701 models miss the radiative effects of overlying humidity on PBL deepening, possibly contributing
702 to the increased climatological Lagrangian deepening seen in models compared to
703 observations.

704 Processes internal to the PBL may contribute to discrepancies in mean behavior, though
705 their linkage to differences seen in Figure 2 are less clear. Models appear to miss aerosol-cloud-
706 precipitation processes when viewed from the Lagrangian reference frame. The aerosol-cloud-
707 lifetime effect appears absent in both models. Further, in many places the response of N_d to
708 predictors disagrees between models and observations. This appears to be a particular
709 weakness in these models, and suggests that further improvements in model microphysics may
710 aid in their performance. Deepening-decoupling processes in the PBL are partially well
711 represented, with clouds breaking up in deep PBLs for all three platforms. However, the
712 coinciding CLWP and N_d behaviors show less agreement, hinting at possible shortcomings in
713 model-produced thermodynamic processes or surface fluxes. The UKMET in particular seems to

714 increase CLWP in deep boundary layers, perhaps failing to properly decouple the cloud from
715 surface moisture sources. It seems likely that the path from sea surface to cloud is not well
716 simulated in models, where clouds are oversensitive to SST and under-sensitive to wind speed.
717 These internal processes need further study in isolation in order to assess their effects on the
718 mean behavior of modeled clouds. It will be necessary to simulate these processes correctly in
719 order to predict systematic cloud responses to climate changes

720

721 *b) Differences in Variables*

722 Due to observational limitations not all model output variables can be easily compared
723 with observations. This is particularly a problem for measurements of CLWP, N_d , and PBL depth.
724 These inconsistencies drive the need for model variables that can be compared more directly
725 with observations in order to eliminate the discrepancies caused by observational issues rather
726 than physical behavior. These discrepancies may partially cause the disagreements seen in
727 Figure 2. Continuing improvements in satellite simulators for GCM output will go a long way
728 towards improving these comparisons. Furthermore, sensor and observation technique
729 improvements will hopefully shrink the wide ranges of variability seen in observations from
730 different sensors in Figures 2b and 2c.

731

732 *c) Future work*

733 The framework presented here can be applied to a limitless number of GCMs in order to
734 test for consistency between models and observations. Future work seeks to streamline our
735 process so that modeling groups can generate trajectories and variables from their model

736 output. By focusing on cloud mechanics on daily timescales, and using a time dimension to
737 directly assess causality, this Lagrangian framework can add value and show which cloud
738 processes are well simulated and which are lacking. Additional comparisons with global cloud-
739 resolving models may help us discern whether cloud responses are controlled by poorly
740 resolved processes. Further, a comparison should be made between a free-running model and
741 the same model with winds nudged by reanalysis fields, hopefully discerning whether cloud
742 responses are due to differing meteorology or model mechanics.

743

744 **5. Conclusions**

745 This Lagrangian analysis compares the time evolution of clouds and cloud variables in
746 several ways. Results appear consistent with the “too few, too bright” issues mentioned in
747 other work with models producing higher N_d and less cloud cover. Cloud tops in the CAM5
748 appear to overshoot the trade inversion by several kilometers, while the observations and
749 UKMET model do not show such extreme vertical development in the subtropics. Lagrangian
750 tendencies of cloud variables and predictor variables are more consistent between platforms,
751 though Lagrangian cloud cover decline and PBL deepening are stronger in the two models than
752 in the observations. A comparison of the time evolution of predictors shows behavior
753 consistent with a transition from a subtropical Sc to a tropical trade Cu environment, with
754 declines in LTS and subsidence and increases in SST.

755 The time evolution of frequency distributions of cloud cover shows that both models
756 generate bimodal distributions of cloud cover with peaks at overcast and below 25% cloud

757 cover. At later times the models tend to increase cloud amounts at the low peak. Observations
758 disagree, showing distributions that tend to change from overcast to merely broken scenes.

759 Despite the differences in the evolution of frequency distributions, the characteristic
760 timescales of cloud cover and CLWP, represented by the e-folding time (τ), shows some
761 consistency between both models and observations. For all three, cloud cover and CLWP have
762 shorter τ , between 11-19 hours, compared to PBL depth, N_d , and rain rates, which were
763 consistently longer in models than observations, though showing more noise and significantly
764 less consistency between platforms.

765 Finally, a comparison of responses to predictors shows that cloud cover and cloud
766 variables in all three platforms are consistently and powerfully affected by $\Delta\omega_{700}$. Increasing
767 ω_{700} drives declines in cloud cover, CLWP, PBL depth, and rain rate. This is opposite from the
768 evolution of the mean state of the Sc-Cu transition where subsidence decreases as clouds
769 decrease, thus this approach allows us to isolate impacts of predictors and test model
770 responses in a way that is not possible using the mean trajectories alone. Free tropospheric
771 humidity drives increases in cloud cover and CLWP for all three platforms, however models do
772 not show that a drier overlying troposphere can lead to PBL deepening, which is shown in
773 observations. Discrepancies in the cloud and cloud variable responses to other meteorological
774 forcings and to internal variables suggests that cloud mechanics are not yet accurately
775 represented in the models, with inconsistent responses to wind speed, SST, and PBL depth. This
776 framework can be applied to any number of climate models in the future to diagnose
777 shortcomings in cloud simulations and compare free-running climate models with those nudged
778 by reanalysis winds.

Cloud Variable	Data Source (observations)				
Cloud	MODIS C6 L3 cloud mask				
CLWP	AMSR/E L3 LWP				
Nd	From MODIS c6 optical properties re and lwp, as in Eastman & Wood (2016)				
PBL	MODIS C6 CTT - ERA-I SST, tuned using CALIPSO VFM, using Eastman et al. (2016) routine				
Rain	AMSR/E 89 GHz Tb, trained using CloudSat				

1136
 1137
 1138 Table 1. A brief list of observed cloud variable sources.
 1139

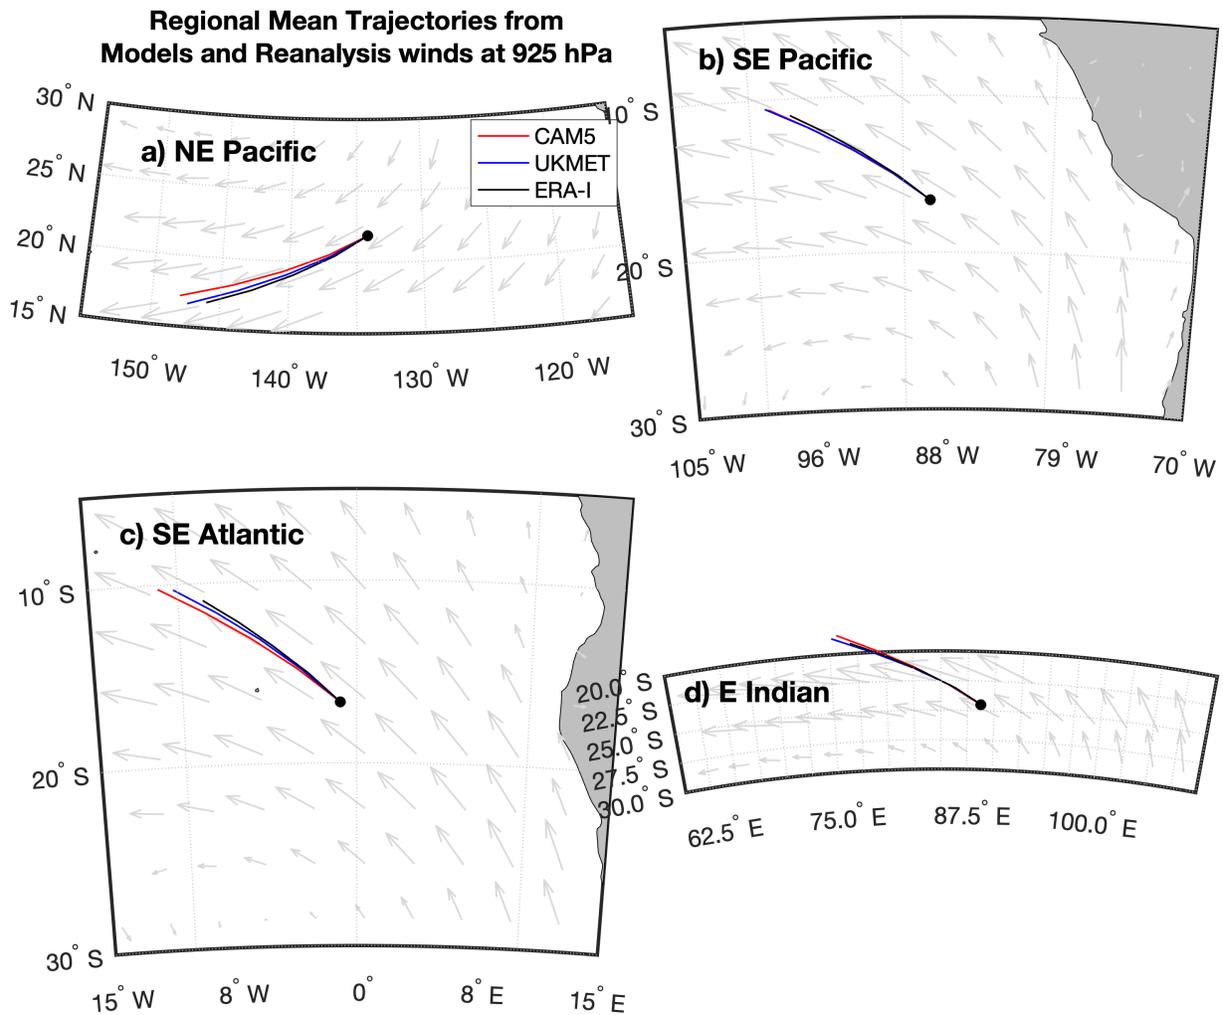

1140
1141

24-hr τ	CAM5	UKMET	OBS
Cloud Cover	15.9	13.4	19.4
CLWP	16.3	13.3	17.5
Nd	57.7	22	21.7
PBL depth	27.1	30.8	23.8
Rain Rate	43.7	66.4	20.2

1142

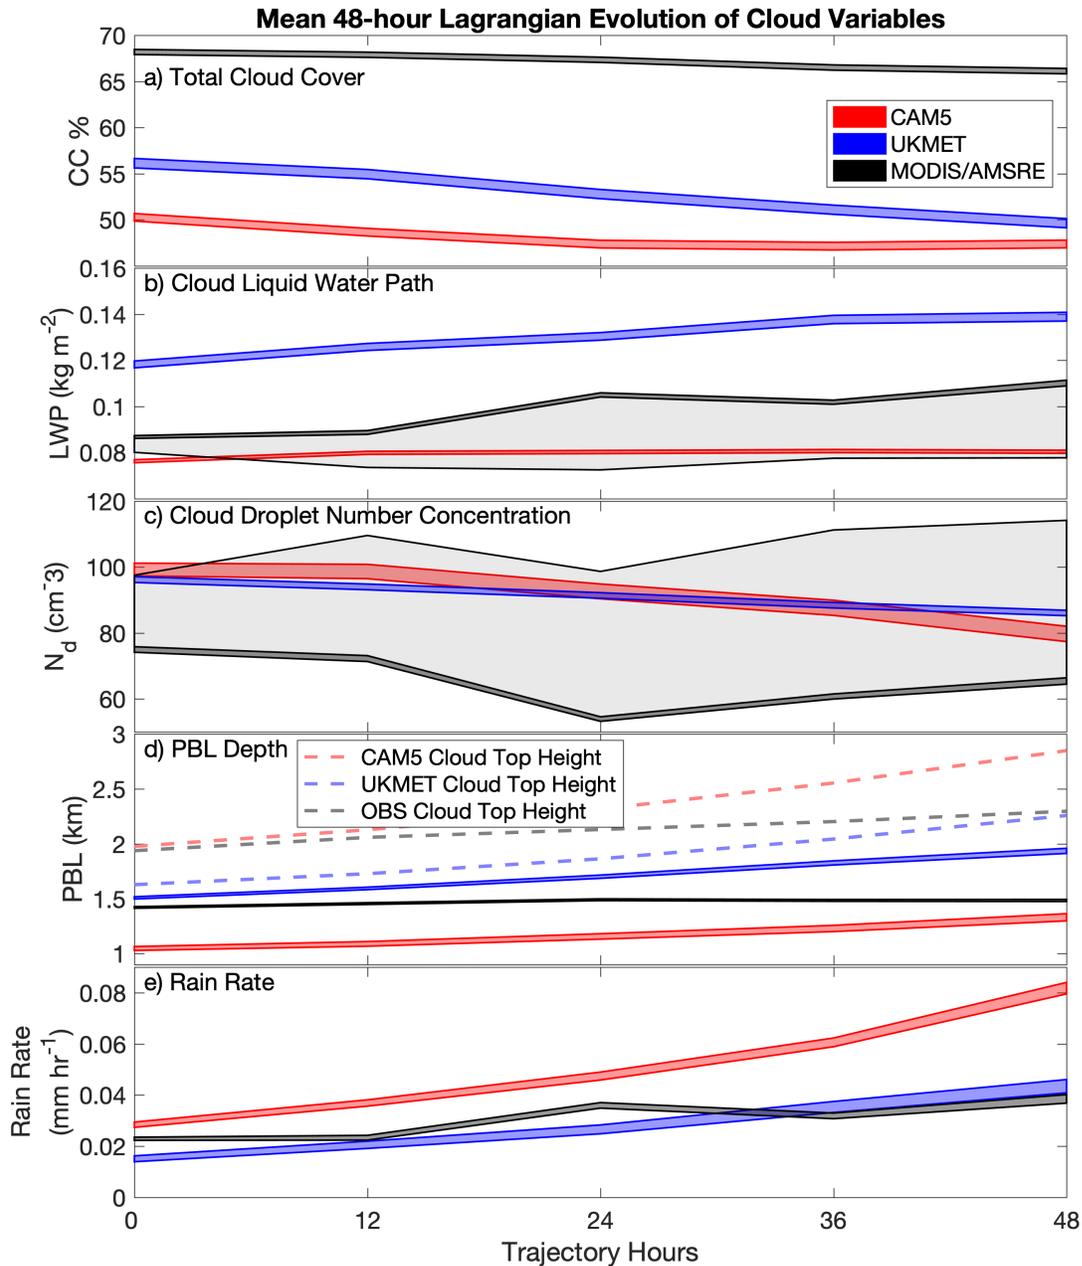

1143 Table 2. e-folding times (τ) estimated using the (red, 24-hour) slopes in Figures 5-7 and
1144 Equation 3. Values of τ represent the time in hours for the lag autocorrelation for a cloud
1145 variable to decline by a factor of $1/e$ as it evolves following the flow.

Figure 1. Composited mean forward-running trajectories from the CAM5 (red), UKMET (blue), and ERA-Interim (black) compared for a single 'launch point' for our four study regions: a) the NE Pacific, b) the SE Pacific, c) the SE Atlantic, and d) the E Indian Ocean. Trajectory beginnings are shown as black circles. Trajectories are all generated using the isobaric wind field at 925 hPa and run forward for 48 hours. Mean wind arrows, shown in gray, are based on the 925 hPa wind field from the ERA-Interim.

Figure 2. The mean 48-hour evolution of our cloud variables: a) cloud cover, b) in-cloud liquid water path, c) droplet number concentration, d) planetary boundary layer depth, and e) rain rate. Means are generated by compositing all available trajectories from all available regions. The (vertical) width of the lines represents the 2σ standard error of the mean. Frame d shows PBL depth along with an estimate of maximum cloud top height based on the highest clouds in models and coldest clouds in the observations. The light gray error bounds in frames b and c represent the multi-sensor variability in CLWP and N_d .

Figure 3. The mean 48-hour evolution of our meteorological predictor variables: f) 10-meter wind speed, g) specific humidity (q) at 700 hPa, h) subsidence at 700 hPa (pressure velocity, ω), i) lower tropospheric stability (the difference in potential temperature, θ , between 700 and 1000 hPa), and j) rain rate. Means are generated by compositing all available trajectories from all available regions. The (vertical) width of the lines represents the 2σ standard error of the mean.

Figure 8. Lines fit to plots of residual cloud cover change as a function of σ -bins of predictor variables, in this case other cloud variables are used as predictors. Lines are generated while holding each of the other predictor variables (both cloud and meteorological) constant. The shaded regions represent the range of slopes produced by holding the predictors constant. Color coding is the same as in previous figures: CAM5 is red, UKMET is blue, and Observations are black.

1207
 1208 Figure 9. Lines fit to plots of residual cloud cover change as a function of σ -bins of predictor
 1209 variables, with meteorological variables external to the cloud deck used as predictors here.
 1210 Lines are generated while holding each of the other predictor variables (both cloud and
 1211 meteorological) constant. The shaded regions represent the range of slopes produced by
 1212 holding the predictors constant. Color coding is the same as in previous figures: CAM5 is red,
 1213 UKMET is blue, and Observations are black.

Figure 10. Bar plots representing slopes as shown in Figures 8 and 9, with error bars representing the range of slopes shown by the shaded regions of Figures 8 and 9. Columns of plots are shown for: a) cloud cover, b) in-cloud liquid water path, c) cloud drop concentration, d) planetary boundary layer depth, and e) rain rates. Bars extending to the right indicate a positive cloud variable response to a 1- σ positive deviation of that predictor variable. Values of σ are constant between the platforms for each predictor, allowing for improved comparability.
